

Bachelier, Louis (1870–1946)

Formation Years

Louis Bachelier was born in Le Havre, France, on March 11, 1870. His father, a native of Bordeaux, moved to Le Havre after his marriage to the daughter of a notable citizen of Le Havre. He started a wine and spirits shop, and bought and exported wines from Bordeaux and Champagne. At the time, Le Havre was an important port. The Protestant bourgeoisie in the city, which dominated the local cotton and coffee markets, occupied the upper echelons of society. The young Louis was educated at a high school in Le Havre. He seems to have been a fairly good student, but he interrupted his studies after earning his high school diploma in 1889, when both of his parents died in the span of a few weeks. To provide for his youngest brother and his older sister, most likely, he took over his father's business, but he sold it after a few years. In 1892, he completed his military service as an infantryman and then moved to Paris, where his activities are unclear. What is clear, however, is that Bachelier focused on his interests in the stock market and undertook university studies at the University of Paris, where in 1895 he obtained his bachelor's degree in the mathematical sciences, without being a particularly distinguished student. After earning his degree, he continued to attend the lectures of the Faculty, including courses in mathematical physics taught by Poincaré and Boussinesq.

Although we cannot be absolutely certain, it is likely that in 1894, Bachelier attended lectures in probability theory given by Poincaré, which were published in 1896 and were based on the remarkable treatise that Joseph Bertrand published in 1888. His attendance at these lectures, his reading of treatises by Bertrand and Poincaré, and his interest in the stock market probably inspired his thesis, "theory of speculation", which was defended by Bachelier [1] in Paris on March 29, 1900, before a jury composed of Appell, Boussinesq, and Poincaré. On the report by Henri Poincaré, he was conferred the rank of Doctor of Mathematics with an "honorable" designation, that is, a designation insufficient for him to obtain employment in higher education, which was extremely limited at the time.

Let us say a few words about this extraordinary thesis. The problem investigated by Bachelier is described in less than a page. The stock market is subject to innumerable random influences, and so it is unreasonable to expect a mathematically precise forecast of stock prices. However, we can try to establish the law of the changes in stock prices over a fixed period of time. The determination of this law was the subject of Bachelier's thesis. The thesis was not particularly original. Since the early nineteenth century, people had applied probability theory to study exchange rates. In France, in particular, we can cite the work of Biquilley (around 1800) or Jules Regnault (around 1850). In his thesis, Bachelier [1] intended to revisit this issue from several viewpoints taken from physics and probability theory, as these subjects were taught in Europe, including Paris, around 1900. He adapted these viewpoints to aid his investigation. The first method he used is the method adopted by Einstein, five years later, to determine the law of Brownian motion in a physical context. It consists of studying the integral equation that governs the probability that the change in price is y at time t , under two natural assumptions: the change in price during two separate time intervals is independent and the expectation of the change in price is zero. The resulting equation is a homogeneous version of the diffusion equation, now known as the *Kolmogorov* (or *Chapman–Kolmogorov*) equation, in which Bachelier boldly asserts that the appropriate solution is given by a centered Gaussian law with variance proportional to time t . He proved a statement already proposed, without justification, by Regnault in 1860 that the expectation of the absolute change in price after time t is proportional to the square root of t .

But this first method, which would eventually be used in the 1930s by physicists and probabilists, did not seem to satisfy Bachelier, since he proposed a second method, which was further developed in the 1930s by the Moscow School: the approximation of the law of Brownian motion by an infinite sequence of coin flips, properly normalized. Since the change in price over a given period of time is the result of a very large number of independent random variables, it is not surprising that this change in price is Gaussian. But the extension of this approximation to a continuous-time version is not straightforward. Bachelier, who already knew the result he wanted to obtain, states and prepares the way to the first known version of a theorem, which in the current

language reads as follows: let $\{X_1, X_2, \dots, X_n, \dots\}$ be a sequence of independent random variables taking values 1 or -1 with probability $1/2$. If we let $S_n = X_1 + \dots + X_n$ and let $[x]$ denote the integer part of a real number x , then

$$\left(\frac{1}{\sqrt{n}} S_{[nt]}, t \geq 0 \right) \longrightarrow (B_t, t \geq 0) \quad (1)$$

in law as $n \longrightarrow \infty$, where $(B_t, t \geq 0)$ is a standard Brownian motion.

This second method, which is somewhat difficult to read and not very rigorous, naturally leads to the previous solution. But it is still not sufficient. Bachelier proposes a third method, the “radiation (or diffusion) of probability”. Bachelier, having attended the lectures of Poincaré and Boussinesq on the theory of heat, was aware of the “method of Laplace”, which gives the fundamental solution of the heat equation, a solution that has exactly the form given by the first (and second) methods used by Bachelier. Hence, there is a coincidence to be elucidated. We know that Laplace probably knew the reason for this coincidence. Lord Rayleigh had recently noticed this coincidence in his solution to the problem of “random phases”. It is likely that neither Bachelier nor Poincaré had read the work of Rayleigh. Anyway, Bachelier, in turn, explains this curious intersection between the theory of heat and the prices of annuities on the Paris stock exchange. This is his third method, which can be summarized as follows.

Consider the game of flipping a fair coin an infinite number of times and set $f(n, x) = \mathbb{P}(S_n = x)$. It has been known since at least the seventeenth century that

$$f(n+1, x) = \frac{1}{2}f(n, x-1) + \frac{1}{2}f(n, x+1) \quad (2)$$

Subtracting $f(n, x)$ from both the sides of the equation, we obtain

$$f(n+1, x) - f(n, x) = \frac{1}{2} \left(f(n, x+1) - 2f(n, x) + f(n, x-1) \right) \quad (3)$$

It then suffices to take the unit 1 in the preceding equation to be infinitely small to obtain the heat equation

$$\frac{\partial f}{\partial n} = \frac{1}{2} \frac{\partial^2 f}{\partial x^2} \quad (4)$$

whose solution is the law of a centered Gaussian random variable with variance n .

Theory of Speculation

At the stock market, probability radiates like heat. This “demonstrates” the role of Gaussian laws in problems related to the stock market, as acknowledged by Poincaré himself in his report: “A little reflection shows that the analogy is real and the comparison legitimate. The arguments of Fourier are applicable, with very little change, to this problem that is so different from the problem to which these arguments were originally applied.” And Poincaré regretted that Bachelier did not develop this point further, though this point would be developed in a masterly way by Kolmogorov in a famous article published in 1931 in the *Mathematische Annalen*. In fact, the first and third methods used by Bachelier are intrinsically linked: the Chapman–Kolmogorov equation for any regular Markov process is equivalent to a partial differential equation of parabolic type. In all regular Markovian schemes that are continuous, probability radiates like heat from a fire fanned by the thousand winds of chance. And further work, exploiting this real analogy, would transform not only the theory of Markov processes but also the century-old theory of Fourier equations and parabolic equations.

Now, having determined the law of price changes, all calculations of financial products involving time follow easily. But Bachelier did not stop there. He proposed a general theory of speculation integrating all stock market products that could be proposed to clients, whose (expected) value at maturity—and therefore whose price—can be calculated using general formulas resulting from theory. The most remarkable product that Bachelier priced was based on the maximum value of a stock during the period between its purchase and a maturity date (usually one month later). In this case, one must determine the law of the maximum of a stock price over some interval of time. This problem would be of concern to Norbert Wiener, the inventor of the mathematical theory of Brownian motion, in 1923. It involves knowing *a priori* the law of the price over an infinite time interval, but it was not known—either in 1923 or in 1900—how to easily calculate the integrals of functions of an infinite number of variables. Let us explain the reasoning used by Bachelier [1] as an example of his methods of analysis.

Bachelier proceeded in two different ways. The first way was based on the second method developed in Bachelier's thesis. It consists of discretizing time in steps of Δt , and introducing a change in price at each step of $\pm \Delta x$. Bachelier wanted to calculate the probability that before time $t = n\Delta t$, the game (or price) exceeds a given value $c = m\Delta x$. Let $n = m + 2p$. Bachelier proposed to first calculate the probability that the price c is reached for the first time at exactly time t . To this end, he uses the gambler's ruin argument: the probability is equal to $(m/n)C_n^p 2^{-n}$, which Bachelier obtained from the ballot formula of Bertrand, which he learned from Poincaré or Bertrand's work, or perhaps both. It suffices to then pass properly to the limit so that $\Delta x = \mathcal{O}(\sqrt{\Delta t})$. One then obtains the probability that the price exceeds c before t . Bachelier then noted that this probability is equal to twice the probability that the price exceeds c at time t .

The result is Bachelier's formula for the law of the maximum M_t of the price B_t over the interval $[0, t]$; that is,

$$\mathbb{P}(M_t > c) = 2\mathbb{P}(B_t > c) \quad (5)$$

It would have been difficult to proceed in a simpler fashion. Having obtained this formula, Bachelier had to justify it in a simple way to understand why it holds. Bachelier therefore added to his first calculation (which was somewhat confusing and difficult to follow) a "direct demonstration" without passing to the limit. He used the argument that "the price cannot pass the threshold c over a time interval of length t without having done so previously" and hence that

$$\mathbb{P}(B_t > c) = \mathbb{P}(M_t > c)\alpha \quad (6)$$

where α is the probability that the price c , having been attained before time t , is greater than c at time t . The latter probability is obviously $1/2$, due to symmetry of the sample paths that go above and that remain below c by time t . And Bachelier concludes: "It is remarkable that the multiple integral that expresses the probability $\mathbb{P}(M_t > c)$ does not seem amenable to ordinary methods of calculation, but can be determined by very simple probabilistic reasoning." It was, without doubt, the first example of the use of the reflection principle in probability theory. In two steps, a complicated calculation yields

a simple formula by using a very simple probabilistic (or combinatorial) argument.

Of course, Bachelier had to do his mathematics without a safety net. What could his safety net have been? The mathematical analysis available during his time could not deal with such strange objects and calculations. It was not until the following year, 1901, that Lebesgue introduced the integral based on the measure that Borel had just recently constructed. The Daniell integral, which Wiener used, dates to 1920 and it was not until the 1930s that European mathematicians realized that computing probabilities with respect to Brownian motion, or with respect to sequences of independent random variables, could be done using Lebesgue measure on the unit interval. Since Lebesgue's theory came to be viewed as one of the strongest pillars of analysis in the twentieth century, this approach gave probability theory a very strong analytic basis. We will have to wait much longer to place the stochastic calculus of Brownian motion and sample path arguments involving stopping times into a relatively uniform analytical framework. Anyway, Bachelier had little concern for either this new theory in analysis or the work of his contemporaries, whom he never cites. He refers to the work of Laplace, Bertrand, and Poincaré, who never cared about the Lebesgue integral, and so Bachelier always ignored its existence.

It seems that in 1900, Bachelier [1] saw very clearly how to model the continuous movement of stock prices and he established new computational techniques, derived notably from the classical techniques involving infinite sequences of fair coin flips. He provided an intermediate mathematical argument to explain a new class of functions that reflected the vagaries of the market, just as in the eighteenth century, when one used geometric reasoning and physical intuition to explain things.

After the Thesis

His Ph.D. thesis defended, Bachelier suddenly seemed to discover the immensity of a world in which randomness exists. The theory of the stock market allowed him to view the classical results of probability with a new eye, and it opened new viewpoints for him. Starting in 1901, Bachelier showed that the known results about infinite sequences of fair coin flips could all (or almost all) be obtained from stock

market theory and that one can derive new results that are more precise than anyone had previously suspected. In 1906, Bachelier proposes an almost general theory of “related probabilities”, that is to say, a theory about what would, 30 years later, be called *Markov processes*. This article by Bachelier was the starting point of a major study by Kolmogorov in 1931 that we already mentioned. All of Bachelier’s work was published with the distant but caring recommendation of Poincaré, so that by 1910, Bachelier, whose income remains unknown and was probably modest, is permitted to teach a “free course” in probability theory at the Sorbonne, without compensation. Shortly thereafter, he won a scholarship that allowed him to publish his *Calculus of Probability*, Volume I, Paris, Gauthier-Villars, 1912 (Volume II never appeared), which included all of his work since his thesis. This very surprising book was not widely circulated in France, and had no impact on the Paris stock market or on French mathematics, but it was one of the sources that motivated work in stochastic processes at the Moscow School in the 1930s. It also influenced work by the American School on sums of independent random variables in the 1950s, and at the same time, influenced new theories in mathematical finance that were developing in the United States. And, as things should rightly be, these theories traced back to France, where Bachelier’s name had become so well recognized that in 2000, the centennial anniversary of his work in “theory of speculation” was celebrated.

The First World War interrupted the work of Bachelier, who was summoned for military service in September 1914 as a simple soldier. When the war ended in December 1918, he was a sublieutenant in the Army Service Corps. He served far from the front, but he carried out his service with honor. As a result, in 1919, the Directorate of Higher Education in Paris believed it was necessary to appoint Bachelier to a university outside of Paris, since the war had decimated the ranks of young French mathematicians and there were many positions to be filled. After many difficulties, due to his marginalization in the French mathematical community and the incongruent nature of his research, Bachelier finally received tenure in 1927 (at the age of 57) as a professor at the University of Besançon, where he remained until his retirement in 1937. Throughout the postwar years,

Bachelier essentially did not publish any original work. He married in 1920, but his wife died a few months later. He was often ill and he seems to have been quite isolated.

In 1937, he moved with his sister to Saint-Malo in Brittany. During World War II, he moved to Saint-Servan, where he died in 1946. He seemed to be aware of the new theory of stochastic processes that was then developing in Paris and Moscow, and that was progressively spreading all over the world. He attempted to claim credit for the things that he had done, without any success. He regained his appetite for research, to the point that in 1941, at the age of 70, he submitted a note for publication to the Academy of Sciences in Paris on the “probability of maximum oscillations”, in which he demonstrated a fine mastery of the theory of Brownian motion, which was undertaken systematically by Paul Levy starting in 1938. Paul Levy, the principal French researcher of the theory of Brownian motion, recognized, albeit belatedly, the work of Bachelier, and his work provided a more rigorous foundation for Bachelier’s “theory of speculation”.

BERNARD BRU

Samuelson, Paul A.

Paul Anthony Samuelson (1915–) is Institute Professor Emeritus at the Massachusetts Institute of Technology where he has taught since 1940. He earned a BA from the University of Chicago in 1935 and his PhD in economics from Harvard University in 1941. He received the John Bates Clark Medal in 1947 and the National Medal of Science in 1996. In 1970, he became the first American to receive the Alfred Nobel Memorial Prize in Economic Sciences. His textbook, *Economics*, first published in 1948, and in its 18th edition, is the best-selling and arguably the most influential economics textbook of all time.

Paul Samuelson is the last great general economist—never again will any one person make such foundational contributions to so many distinct areas of economics. His prolific and profound theoretical contributions over seven decades of published research have been universal in scope, and his ramified influence on the whole of economics has led to foundational contributions in virtually every field of economics, including financial economics. Representing 27 years of scientific writing from 1937 to the middle of 1964, the first two volumes of his *Collected Scientific Papers* contain 129 articles and 1772 pages. These were followed by the publication of the 897-page third volume in 1972, which registers the succeeding seven years' product of 78 articles published when he was between the ages of 49 and 56 [18]. A mere five years later, at the age of 61, Samuelson had published another 86 papers, which fill the 944 pages of the fourth volume. A decade later, the fifth volume appeared with 108 articles and 1064 pages. A glance at his list of publications since 1986 assures us that a sixth and even seventh volume could be filled. That Samuelson paid no heed to the myth of debilitating age in science is particularly well-exemplified in his contributions to financial economics, with all but 6 of his more than 60 papers being published after he had reached the age of 50.

Samuelson's contribution to quantitative finance, as with mathematical economics generally, has been foundational and wide-ranging: these include reconciling the axioms of expected utility theory first with nonstochastic theories of choice [9] and then with the ubiquitous and practical mean–variance criterion of choice [16], exploring the foundations of diversification [13] and optimal portfolio selection when facing

fat-tailed, infinite-variance return distributions [14], and, over a span of nearly four decades, analyzing the systematic dependence on age of optimal portfolio strategies, in particular, optimal long-horizon investment strategies, and the improper use of the Law of Large Numbers to arrive at seemingly dominating strategies for the long run [10, 15, 17, 21–27]. In investigating the oft-told tale that investors become systematically more conservative as they get older, Samuelson shows that perfectly rational risk-averse investors with constant relative risk aversion will select the same fraction of risky stocks *versus* safe cash period by period, independently of age, provided that the investment opportunity set is unchanging. Having shown that greater investment conservatism is not an inevitable consequence of aging, he later [24] demonstrates conditions under which such behavior can be optimal: with mean-reverting changing opportunity sets, older investors will indeed be more conservative than in their younger days, provided that they are more risk averse than a growth-optimum, log-utility maximizer. To complete the rich set of age-dependent risk-taking behaviors, Samuelson shows that rational investors may actually become less conservative with age, if either they are less risk averse than log or if the opportunity set follows a trending, momentum-like dynamic process. He recently confided that in finance, this analysis is a favorite brainchild of his.

Published in the same issue of the *Industrial Management Review*, “Proof That Properly Anticipated Prices Fluctuate Randomly” and “Rational Theory of Warrant Pricing” are perhaps the two most influential Samuelson papers in quantitative finance. During the decade before their printed publication in 1965, Samuelson had set down, in an unpublished manuscript, many of the results in these papers and had communicated them in lectures at MIT, Yale, Carnegie, the American Philosophical Society, and elsewhere. In the early 1950s, he supervised a PhD thesis on put and call pricing [5].

The sociologist or historian of science would undoubtedly be able to develop a rich case study of alternative paths for circulating scientific ideas by exploring the impact of this oral publication of research in rational expectations, efficient markets, geometric Brownian motion, and warrant pricing in the period between 1956 and 1965.

Samuelson (1965a) and Eugene Fama independently provide the foundation of the Efficient Market

theory that developed into one of the most important concepts in modern financial economics. As indicated by its title, the principal conclusion of the paper is that in well-informed and competitive speculative markets, the intertemporal changes in prices will be essentially random. Samuelson has described the reaction (presumably his own as well as that of others) to this conclusion as one of “initial shock—and then, upon reflection, that it is obvious”. The argument is as follows: the time series of changes in most economic variables gross national product (GNP, inflation, unemployment, earnings, and even the weather) exhibit cyclical or serial dependencies. Furthermore, in a rational and well-informed capital market, it is reasonable to presume that the prices of common stocks, bonds, and commodity futures depend upon such economic variables. Thus, the shock comes from the seemingly inconsistent conclusion that in such well-functioning markets the changes in speculative prices should exhibit no serial dependencies. However, once the problem is viewed from the perspective offered in the paper, this seeming inconsistency disappears and all becomes obvious.

Starting from the consideration that in a competitive market, if everyone *knew* that a speculative security was expected to rise in price by more (less) than the required or fair expected rate of return, it would *already* be bid up (down) to negate that possibility, Samuelson postulates that securities will be priced at each point in time so as to yield this fair expected rate of return. Using a backward-in-time induction argument, he proves that the changes in speculative prices around that fair return will form a *martingale*. And this follows no matter how much serial dependency there is in the underlying economic variables upon which such speculative prices are formed. In an informed market, therefore, current speculative prices will already reflect anticipated or forecastable future changes in the underlying economic variables that are relevant to the formation of prices, and this leaves only the unanticipated or unforecastable changes in these variables as the sole source of fluctuations in speculative prices.

Samuelson is careful to warn the reader against interpreting his mathematically derived theoretical conclusions about markets as empirical statements. Nevertheless, for 40 years, his model has been important to the understanding and interpretation of the empirical results observed in real-world markets. For

the most part in those ensuing years, his interpretation of the data is that organized markets where widely owned securities are traded are well approximated as *microefficient*, meaning that the relative pricing of individual securities within the same or very similar asset classes is such that active asset management applied to those similar securities (e.g., individual stock selection) does not earn greater risk-adjusted returns.

However, Samuelson is discriminating in his assessment of the efficient market hypothesis as it relates to real-world markets. He notes a list of the “few not-very-significant apparent exceptions” to microefficient markets [23, p. 5]. He also expresses belief that there are exceptionally talented people who can probably garner superior risk-corrected returns, and even names a few. He does not see them as offering a practical broad alternative investment prescription for active management since such talents are few and hard to identify. As Samuelson believes strongly in microinefficiency of the markets, he expresses doubt about *macromarket* efficiency: namely that indeed asset-value “bubbles” do occur.

There is no doubt that the mainstream of the professional investment community has moved significantly in the direction of Paul Samuelson’s position during the 35 years since he issued his challenge to that community to demonstrate widespread superior performance [20]. Indexing as either a core investment strategy or a significant component of institutional portfolios is ubiquitous, and even among those institutional investors who believe they can deliver superior performance, performance is typically measured incrementally relative to an index benchmark and the expected performance increment to the benchmark is generally small compared to the expected return on the benchmark itself. It is therefore with no little irony that as investment practice has moved in this direction, for the last 15 years, academic research has moved in the opposite direction, strongly questioning even the microinefficiency case for the efficient market hypothesis. The conceptual basis of these challenges comes from theories of asymmetric information and institutional rigidities that limit the arbitrage mechanisms that enforce microinefficiency and of cognitive dissonance and other systematic behavioral dysfunctions among individual investors that purport to distort market prices away from rationally determined asset prices in identified ways. A substantial quantity of empirical

evidence has been assembled, but there is considerable controversy over whether it does indeed make a strong case to reject market microefficiency in the Samuelsonian sense. What is not controversial at all is that Paul Samuelson's efficient market hypothesis has had a deep and profound influence on finance research and practice for more than 40 years and all indications are that it will continue to do so well into the future.

If one were to describe the 1960s as "the decade of capital asset pricing and market efficiency" in view of the important research gains in quantitative finance during then, one need hardly say more than "the Black-Scholes option pricing model" to justify describing the 1970s as "the decade of option and derivative security pricing." Samuelson was ahead of the field in recognizing the arcane topic of option pricing as a rich area for problem choice and solution. By at least the early 1950s, Samuelson had shown that the assumption of an absolute random walk or arithmetic Brownian motion for stock price changes leads to absurd prices for long-lived options, and this was done before his rediscovery of Bachelier's pioneering work [1] in which this very assumption is made. He introduced the alternative process of a "geometric" Brownian motion in which the log of price changes follows a Brownian motion, possibly with a drift. His paper on the rational theory of warrant pricing [12] resolves a number of apparent paradoxes that had plagued the existing mathematical theory of option pricing from the time of Bachelier. In the process (with the aid of a mathematical appendix provided by H. P. McKean, Jr), Samuelson also derives much of what has become the basic mathematical structure of option pricing theory today.

Bachelier [1] considered options that could only be exercised on the expiration date. In modern times, the standard terms for options and warrants permit the option holder to exercise on or before the expiration date. Samuelson coined the terms *European* option to refer to the former and *American* option to refer to the latter. As he tells the story, to get a practitioner's perspective in preparation for his research, he went to New York to meet with a well-known put and call dealer (there were no traded options exchanges until 1973) who happened to be Swiss. Upon his identifying himself and explaining what he had in mind, Samuelson was quickly told, "You are wasting your time—it takes a *European* mind to understand options." Later on, when writing

his paper, Samuelson thus chose the term *European* for the relatively simple(-minded)-to-value option contract that can only be exercised at expiration and *American* for the considerably more(-complex)-to-value option contract that could be exercised early, any time on or before its expiration date.

Although real-world options are almost always of the American type, published analyses of option pricing prior to his 1965 paper focused exclusively on the evaluation of European options and therefore did not include the extra value to the option from the right to exercise early.

The most striking comparison to make between the Black-Scholes option pricing theory and Samuelson's *rational theory* [12] is the formula for the option price. The Samuelson partial differential equation for the option price is the same as the corresponding equation for the Black-Scholes option price *if* one sets the Samuelson parameter for the expected return on the underlying stock equal to the riskless interest rate minus the dividend yield and sets the Samuelson parameter for the expected return on the option equal to the riskless interest rate. It should, however, be underscored that the mathematical equivalence between the two formulas with the redefinition of parameters is purely a formal one. The Samuelson model simply posits the expected returns for the stock and option. By employing a dynamic hedging or replicating portfolio strategy, the Black-Scholes analysis derives the option price without the need to know either the expected return on the stock or the required expected return on the option. Therefore, the fact that the Black-Scholes option price satisfies the Samuelson formula implies neither that the expected returns on the stock and option are equal nor that they are equal to the riskless rate of interest. Furthermore, it should also be noted that Black-Scholes pricing of options does not require knowledge of investors' preferences and endowments as is required, for example, in the sequel Samuelson and Merton [28] warrant pricing paper. The "rational theory" put forward in 1965 is thus clearly a "miss" with respect to the Black-Scholes development. However, as this analysis shows, it is just as clearly a "near miss". See [6, 19] for a formal comparison of the two models.

Extensive reviews of Paul Samuelson's remarkable set of contributions to quantitative finance can be found in [2–4, 7, 8].

ROBERT C. MERTON

Black, Fischer

The central focus of the career of Fischer Black (1938–1995) was on teasing out the implications of the capital asset pricing model (CAPM) for the changing institutional framework of financial markets of his day. He became famous for the Black–Scholes options formula [14], an achievement that is now widely recognized as having opened the door to modern quantitative finance and financial engineering. Fischer was the first quant, but a very special kind of quant because of his taste for the big picture [16].

Regarding that big picture, as early as 1970, he sketched a vision of the future that has by now largely come true:

Thus a long term corporate bond could actually be sold to three separate persons. One would supply the money for the bond; one would bear the interest rate risk; and one would bear the risk of default. The last two would not have to put up any capital for the bonds, although they might have to post some sort of collateral.

Today we recognize the last two instruments as an interest rate swap and a credit default swap, the two instruments that have been the central focus of financial engineering ever since.

All of the technology involved in this engineering can be traced back to roots in the original Black–Scholes option pricing formula [14]. Black himself came up with a formula through CAPM, by thinking about the exposure to systemic risk that was involved in an option, and how that exposure changes as the price of the underlying changes. Today the formula is more commonly derived using the Ito formula and the option replication idea introduced by Merton [17]. For a long time, Black himself was unsure about the social utility of equity options. If all they do is to allow people to achieve the same risk exposure they could achieve by holding equity outright with leverage, then what is the point?

The Black–Scholes formula and the hedging methodology behind it subsequently became a central pillar in the pricing of contingent claims of all kinds and in doing so gave rise to many innovations that contributed to making the world more like his 1970 vision. Black and Cox [9] represents an early attempt to use the option pricing technology to price default risk. Black [4] similarly uses the option pricing technology to price currency risk. Perhaps, Black's most

important use of the tools was in his work on interest rate derivatives, in the famous Black–Derman–Toy term structure model [10].

Black got his start in finance after already earning his PhD in applied mathematics (Harvard, 1964) when he learned about CAPM from Treynor [18], his colleague at the business consulting firm Arthur D. Little, Inc. Fischer had never taken a single course in economics or finance, nor did he ever do so subsequently. Nevertheless, the field was underdeveloped at the time, and Fischer managed to set himself up as a financial consultant and to parlay his success in that capacity into a career in academia (University of Chicago 1971–1975, Massachusetts Institute of Technology 1975–1984), and then into a partnership at the Wall Street investment firm of Goldman Sachs (1984–1995). There can be no doubt that his early success with the options pricing formula opened these doors. The more important point is how, in each of these settings, Fischer used the opportunity he had been given to help promote his vision of a CAPM future for the financial side of the economy.

CAPM is only about a world of debt and equity, and the debt in that world is both short term and risk free. In such a world, everyone holds the fully diversified market portfolio of equity and then adjusts risk exposure by borrowing or lending in the market for risk-free debt. As equity values fluctuate, outstanding debt also fluctuates, as people adjust their portfolios to maintain desired risk exposure. One implication of CAPM, therefore, is that there should be a market for passively managed index mutual funds [15]. Another implication is that the regulatory apparatus surrounding banking, both lending and deposit taking, should be drastically relaxed to facilitate dynamic adjustment of risk exposure [3]. And yet a third implication is that there might be a role for an automatic risk rebalancing instrument, essentially what is known today as *portfolio insurance* [6, 13].

Even while Black was working on remaking the world in the image of CAPM, he was also expanding the image of the original CAPM to include a world without a riskless asset in his famous zero-beta model [1] and to include a world with multiple currencies in his controversial universal hedging model [2, 7] that subsequently formed the analytical core of the Black–Litterman model of global asset allocation [11, 12].

These and other contributions to quantitative finance made Fischer Black famous, but according

to him, his most important work was the two books he wrote that extended the image of CAPM to the real economy, including the theory of money and business cycles [5, 8]. The fluctuation of aggregate output, he reasoned, was nothing more than the fluctuating yield on the national stock of capital. Just as risk is the price we pay for higher expected yield, business fluctuation is also the price we pay for higher expected rates of economic growth.

The rise of modern finance in the last third of twentieth century transformed the financial infrastructure within which businesses and households interact. A system of banking institutions was replaced by a system of capital markets, as financial engineering developed ways to turn loans into bonds. This revolution in institutions has also brought with it a revolution in our thinking about how the economy works, including the role of government regulation and stabilization policy. Crises in the old banking system gave rise to the old macroeconomics. Crises in the new capital markets system will give rise to a new macroeconomics, possibly built on the foundations laid by Fischer Black.

PERRY MEHRLING

Mandelbrot, Benoit

Benoit B. Mandelbrot, Sterling Professor Emeritus of Mathematical Sciences at Yale University and IBM Fellow Emeritus at the IBM Research Center, best known as the “father of fractal geometry”, is a Polish-born French-American multidisciplinary scientist with numerous contributions to different fields of knowledge including mathematics, statistics, hydrology, physics, engineering, physiology, economics and, last but not least, quantitative finance. In this short text we will focus on Mandelbrot’s contributions to the study of financial markets.

Benoit Mandelbrot was born in Warsaw, Poland, on November 20, 1924 in a family of scholars from Lithuania. In 1936 Mandelbrot’s family moved to Paris, where he was influenced by his mathematician uncle Szolem Mandelbrojt (1899–1983). He entered the Ecole Polytechnique in 1944. Among his professors at Polytechnique was Paul Levy, whose pioneering work on stochastic processes influenced Mandelbrot.

After two years in Caltech and after obtaining a doctoral degree in mathematics from University of Paris in 1952, he started his scientific career at the Centre National de la Recherche Scientifique in Paris, before moving on various scientific appointments which included those at Ecole Polytechnique, Université de Lille, the University of Geneva MIT, Princeton, University of Chicago, and finally the IBM Thomas J. Watson Research Center in Yorktown Heights, New York and Yale University where he spent the longer part of his career.

A central thread in his scientific career is the “ardent pursuit of the concept of roughness” which resulted in a rich theoretical apparatus—fractal and multifractal geometry—whose aim is to describe and represent the order hidden in apparently wildly

disordered and random phenomena ranging from the geometry of coastlines to the variation of foreign exchange rates. In his own words

The roughness of clusters in the physics of disorder, of turbulent flows, of exotic noises, of chaotic dynamical systems, of the distribution of galaxies, of coastlines, of stock price charts, and of mathematical constructions,—these have typified the topics I studied.

He formalized the notion of ‘fractal process’—and later, that of multifractal [13]—which provided a tool for quantifying the “degree of irregularity” of various random phenomena in mathematics, physics, and economics.

Benoit Mandelbrot’s numerous awards include the 1993 *Wolf Prize for Physics* and the 2003 *Japan Prize for Science and Technology*, the 1985 *F. Barnard Medal for Meritorious Service to Science* (“*Magna est Veritas*”) of the US National Academy of Sciences, the 1986 *Franklin Medal for Signal and Emergent Service in Science* of the Franklin Institute of Philadelphia, the 1988 *Charles Proteus Steinmetz Medal* of IEEE, the 2004 *Prize of Financial Times/Deutschland*, and a *Humboldt Preis* from the Alexander von Humboldt Stiftung.

From Mild to Wild Randomness: The Noah Effect

Mandelbrot developed an early interest in the stochastic modeling of financial markets. Familiar with the work of Louis Bachelier (see **Bachelier, Louis (1870–1946)**), Mandelbrot published a series of pioneering studies [6–8, 21] on the tail behavior of the distribution of price variations, where he advocated the use of heavy-tailed distributions and scale-invariant Lévy processes for modeling price fluctuations. The discovery of the heavy-tailed nature of price movements led him to coin the term “wild randomness” for describing market behavior, as opposed to the “mild randomness” represented by Bachelier’s Brownian model, which later became the standard approach embodied in the Black–Scholes model. Mandelbrot likened the sudden bursts of volatility in financial markets to the “Noah effect”, by analogy with the flood which destroys the world in Noah’s biblical story:

In science, all important ideas need names and stories to fix them in the memory. It occurred to

me that the market's first wild trait, abrupt change or discontinuity, is prefigured in the tale of Noah. As Genesis relates, in Noah's six-hundredth year God ordered the Great Flood to purify a wicked world. [...] The flood came and went, catastrophic but transient. Market crashes are like that : at times, even a great bank or brokerage house can seem like a little boat in a big storm.

Long-range Dependence: The Joseph Effect

Another early insight of Mandelbrot's studies of financial and economic data was the presence of long-range dependence [9–11] in market fluctuations:

The market's second wild trait—almost cycles—is prefigured in the story of Joseph. The Pharaoh dreamed that seven fat cattle were feeding in the meadows, when seven lean kine rose out of the Nile and ate them. [...] Joseph, a Hebrew slave, called the dreams prophetic : Seven years of famine would follow seven years of prosperity. [...] Of course, this is not a regular or predictable pattern. But the appearance of one is strong. Behind it is the influence of long-range dependence in an otherwise random process or, put another way, a long-term memory through which the past continues to influence the random fluctuations of the present. I called these two distinct forms of wild behavior the Noah effect and the Joseph effect. They are two aspects of one reality.

Building on his earlier work Mandelbrot [22, 23] on long-range dependence in hydrology and fractional Brownian motion, he proposed the use of fractional processes for modeling long-range dependence and scaling properties of economic quantities (*see Long Range Dependence*).

Multifractal Models and Stochastic Time Changes

In a series of papers [2, 4, 20] with Adlai Fisher and Laurent Calvet, Mandelbrot studied the scaling properties of the US/DEM foreign exchange rate at frequencies ranging from a few minutes to weeks and, building on earlier work by Clark [3] and Mandelbrot [12, 13], introduced a new family of stochastic models, where the (log) price of an asset is represented by a time-changed fractional Brownian motion, where the time change, representing market

activity, is given by a multifractal (*see Multifractals*) increasing process (*see Mixture of Distribution Hypothesis; Time Change*) [5, 15]:

The key step is to introduce an auxiliary quantity called *trading time*. The term is self-explanatory and embodies two observations. While price changes over fixed clock time intervals are long-tailed, price changes between successive transactions stay near-Gaussian over sometimes long period between discontinuities. Following variations in the trading volume, the time interval between successive transactions vary greatly. This suggests that trading time is related to volume.

The topic of multifractal modeling in finance was further developed in [1, 17–19]; a nontechnical account is given in [16].

Mandelbrot's work in quantitative finance has been generally 20 years ahead of its time: many of his ideas proposed in the 1960s—such as long-range dependence, volatility clustering, and heavy tails—became mainstream in financial modeling in the 1990s. If this is anything of a pattern, his more recent work in the field might deserve a closer look. Perhaps, one of the most important insights of his work on financial modeling is to *closely examine* the empirical features of data before axiomatizing and writing down complex equations, a timeless piece of advice which can be a useful guide for quantitative modeling in finance.

Mandelbrot's work in finance is summarized in the books [14, 15] and a popular account of this work is given in the book [5].

RAMA CONT

Sharpe, William F.

William Forsyth Sharpe (born on June 16, 1934) is one of the leading contributors to financial economics and shared the Nobel Memorial Prize in Economic Sciences in 1990 with **Harry Markowitz** and Merton Miller. His most important contribution is the **capital asset pricing model** (CAPM), which provided an equilibrium-based relationship between the expected return on an asset and its risk as measured by its covariance with market portfolio. Similar ideas were developed by John Lintner, Jack Treynor (*see Treynor, Lawrence Jack*), and Jan Mossin around the same time. Sharpe has made other important contributions to the field of financial economics but, given the space limitations, we only describe two of his contributions: the CAPM and the Sharpe ratio.

It is instructive to trace the approach used by Sharpe in developing the CAPM. His starting point was Markowitz's model of portfolio selection, which showed how rational investors would select optimal portfolios. If investors only care about the expected return and the variance of their portfolios, then the optimal weights can be obtained by quadratic programming. The inputs to the optimization are the expected returns on the individual securities and their covariance matrix. In 1963, Sharpe [1] showed how to simplify the computations required under the Markowitz approach. He assumed that each security's return was generated by two random factors: one common to all securities and a second factor that was uncorrelated across securities. This assumption leads to a simple diagonal covariance matrix. Although the initial motivation for this simplifying assumption was to reduce the computational time, it would turn out to have deep economic significance.

These economic ideas were developed in Sharpe's [2] *Journal of Finance* paper. He assumed that all investors would select mean-variance-efficient portfolios. He also assumed that investors had homogeneous beliefs and that investors could borrow and lend at the same riskless rate. As Tobin had shown, this implied two fund separations where the investor would divide his money between the risk-free asset and an efficient portfolio of risky assets. Sharpe highlighted the importance of the notion of equilibrium in this context. This efficient portfolio of risky assets in equilibrium can be identified with the

market portfolio. Sharpe's next step was to derive a relationship between the expected return on any risky asset and the expected return on the market. As a matter of curiosity, the CAPM relationship does not appear in the body of the paper but rather as the final equation in footnote 23 on page 438.

The CAPM relationship in modern notation is

$$E[R_j] - r_f = \beta_j (E[R_m] - r_f) \quad (1)$$

where R_j is the return on security j , R_m is the return on the market portfolio of all risky assets, r_f is the return on the risk-free security, and

$$\beta_j = \frac{\text{Cov}(R_j, R_m)}{\text{Var}(R_m)} \quad (2)$$

is the *beta* of security j . The CAPM asserts that the excess expected return on a risky security is equal to the security's beta times the excess expected return on the market. Note that this is a single period model and that it is formulated in terms of *ex ante* expectations. Note also that formula (2) provides an explicit expression for the risk of a security in terms of its covariance with the market and the variance with the market.

The CAPM has become widely used in both investment finance and corporate finance. It can be used as a tool in portfolio selection and also in the measurement of investment performance of portfolio managers. The CAPM is also useful in capital budgeting applications since it gives a formula for the required expected return on an investment. For this reason, the CAPM is often used in rate hearings in some jurisdictions for regulated entities such as utility companies or insurance companies.

The insights from the CAPM also played an important role in subsequent theoretical advances, but owing to space constraint we only mention one. The original derivation of the classic Black–Scholes option formula was based on the CAPM. Black assumed that the return on the stock and the return on its associated warrant both obeyed the CAPM. Hence he was able to obtain expressions for the expected return on both of these securities and he used this in deriving the Black–Scholes equation for the warrant price.

The second contribution that we discuss is the Sharpe ratio. In the case of a portfolio p with expected return $E[R_p]$ and standard deviation σ_p , the

Sharpe ratio is

$$\frac{E[R_p] - r_f}{\sigma_p} \quad (3)$$

Sharpe [3] introduced this formula in 1966. It represents the excess expected return on the portfolio normalized by the portfolio's standard deviation and thus provides a compact measure of the reward to variability. The Sharpe ratio is also known as the market price of risk. Sharpe used this ratio to evaluate the performance of mutual funds, and it is now widely used as a measure of portfolio performance.

In continuous time finance, the instantaneous Sharpe ratio, γ_t , plays a key role in the transformation of a Brownian motion under the real-world measure P to a Brownian motion under the risk neutral measure Q . Suppose W_t is a Brownian motion under P and $\tilde{W}_t$ is a Brownian motion under Q , then we have, from the Girsanov theorem under suitable conditions, on γ

$$d\tilde{W}_t = dW_t + \gamma_t dt \quad (4)$$

It is interesting to see that the Sharpe ratio figures so prominently in this fundamental relationship in modern mathematical finance.

Bill Sharpe has made several other notable contributions to the development of the finance field. His papers have profoundly influenced investment science and portfolio management. He developed the first binomial tree model (see **Binomial Tree**) for option pricing, the gradient method for asset

allocation optimization and returns-based **style analysis** for evaluating the style and performance of investment funds. Sharpe has helped translate these theoretical ideas into practical applications. These applications include the creation of index funds and several aspects of retirement portfolio planning. He has written a number of influential textbooks, including *Investments*, used throughout the world. It is clear that Sharpe's ideas have been of great significance in the subsequent advances in the discipline of finance.

Markowitz, Harry

♣ Harry Max Markowitz, born in Chicago in 1927, said in his 1990 Nobel Prize acceptance speech that, as a child, he was unaware of the Great Depression, which caused a generation of investors and noninvestors the world over to mistrust the markets. However, it was a slim, 15-page paper published by Markowitz as a young man that would eventually transform the way people viewed the relationship between risk and return, and that overhauled the way the investment community constructed diversified portfolios of securities.

Markowitz was working on his dissertation in economics at the University of Chicago when his now-famous “Portfolio Selection” paper appeared in the March 1952 issue of the *Journal of Finance* [1]. He was 25. He went on to win the Nobel Prize in Economic Sciences in 1990 for providing the cornerstone to what came to be known as *modern portfolio theory* (**Modern Portfolio Theory**).

Markowitz shared the Nobel Prize with Merton H. Miller and William F. Sharpe (**Sharpe, William F.**), who were recognized, respectively, for their work on how firms’ capital structure and dividend policy affect their stock price, and the development of the capital asset pricing model, which presents a way to measure the riskiness of a stock relative to the performance of the stock market as a whole. Together, the three redefined the way investors thought about the investment process, and created the field of financial economics. Markowitz, whose work built on earlier work on diversification by Yale University’s James Tobin, who received a Nobel Prize in 1981, was teaching at Baruch College at the City University of New York when he won the Nobel at the age of 63.

Markowitz received a bachelor of philosophy in 1947 and a PhD in economics in 1955, both from the University of Chicago. Years later he said that when he decided to study economics, his philosophical interests drew him toward the “economics of uncertainty”. At Chicago, he studied with Milton Friedman, Jacob Marschak, Leonard Savage, and Tjalling Koopmans, and became a student member of the famed Cowles Commission for Research in Economics (which moved to Yale University in 1955 and was renamed the Cowles Foundation).

The now-landmark 1952 “Portfolio Selection” paper skipped over the problem of selecting individual stocks and focused instead on how a manager or investor selects a portfolio best suited to the individual’s risk and return preferences. Pre-Markowitz, diversification was considered important, but there was no framework to determine how diversified a portfolio was or how an investor could create a well-diversified portfolio.

Keeping in mind that “diversification is both observed and sensible,” the paper began from the premise that investors consider expected return a “desirable thing” and risk an “undesirable thing”. Markowitz’s first insight was to look at a portfolio’s risk as the variance of its returns. This offered a way to quantify investment risk that previously had not existed. He then perceived that a portfolio’s riskiness depended not just on the expected returns and variances of the individual assets but also on the correlations between the assets in the portfolio. For Markowitz, the wisdom of diversification was not simply a matter of holding a large number of different securities, but of holding securities whose value did not rise and fall in tandem with one another. “It is necessary to avoid investing in securities with high covariances among themselves,” he stated in the paper. Investing in companies in different industries, for instance, increased a portfolio’s diversification and, paradoxically, improved the portfolio’s expected returns by reducing its variance.

Markowitz’s paper laid out a mathematical theory for deriving the set of optimal portfolios based on their risk-return characteristics. Markowitz showed how mean-variance analysis could be used to find a set of securities whose risk-return combinations were deemed “efficient”. Markowitz referred to this as the expected returns–variance of returns rule (E-V rule). The range of possible risk–return combinations yielded what Markowitz described as efficient and inefficient portfolios, an idea he based on Koopmans’ notion that there are efficient and inefficient allocations of resources [3]. Koopmans, at the time, was one of Markowitz’s professors. Markowitz’s notion of efficient portfolios was subsequently called the *efficient frontier*. “Not only does the E-V hypothesis imply diversification, it implies the ‘right kind’ of diversification for the ‘right reason,’” Markowitz wrote. The optimal portfolio was the one that would provide the minimum risk for a

given expected return, or the highest expected return for a given level of risk. An investor would select the portfolio whose risk-return characteristics he preferred.

It has been said many times over the years that Markowitz's portfolio theory provided, at long last, the math behind the adage "Don't put all your eggs in one basket." In 1988, Sharpe said of Markowitz's portfolio selection concept: "I liked the parsimony, the beauty, of it. . . . I loved the mathematics. It was simple but elegant. It had all the aesthetic qualities that a model builder likes" [5].

Back in 1952, Markowitz already knew the practical value of the E-V rule he had crafted. It functioned, his paper noted, both "as a hypothesis to explain well-established investment behavior and as a maxim to guide one's own action." However, Markowitz's insight was deeper. The E-V rule enabled the investment management profession to distinguish between investment and speculative behavior, which helped fuel the gradual institutionalization of the investment management profession. In the wake of Markowitz's ideas, investment managers could strive to build portfolios that were not simply groupings of speculative stocks but well-diversified sets of securities designed to meet the risk-return expectations of investors pursuing clear investment goals.

Markowitz's ideas gained traction slowly, but within a decade investment managers were turning to Markowitz's theory of portfolio selection (**Modern Portfolio Theory**) to help them determine how to select portfolios of diversified securities. This occurred as institutional investors in the United States were casting around for ways to structure portfolios that relied more on analytics and less on relationships with brokers and bankers. In the intervening years, Markowitz expanded his groundbreaking work. In 1956, he published the Critical Line Algorithm, which explained how to compute the efficient frontier for portfolios with large numbers of securities subject to constraints. In 1959, he published *Portfolio Selection: Efficient Diversification of Investments*, which bored further into the subject and explored the relationship between his mean-variance analysis and the fundamental theories of action under uncertainty of John von Neumann and Oskar Morgenstern, and of Leonard J. Savage [2].

However, while Markowitz is most widely known for his work in portfolio theory, he has said that

he values another prize he received more than the Nobel: the von Neumann Prize in operations research theory. That prize, he said, recognized the three main research areas that have defined his career. Markowitz received the von Neumann prize in 1989 from the Operations Research Society of America and the Institute of Management Sciences (now combined as INFORMS) for his work on portfolio theory, sparse matrix techniques and the high-level simulation language called *SIMSCRIPT programming language*.

After Chicago, Markowitz went to the RAND Corp. in Santa Monica, CA, where he worked with a group of economists on linear programming techniques. In the mid-1950s, he developed sparse matrices, a technique to solve large mathematical optimization problems. Toward the end of the decade, he went to General Electric to build models of manufacturing plants in the company's manufacturing services department. After returning to RAND in 1961, he and his team developed a high-level programming language for simulations called *SIMSCRIPT* to support Air Force projects that involved simulation models. The language was published in 1962. The same year, Markowitz and former colleague Herb Karr formed CACI, the California Analysis Center Inc. The firm later changed its name to Consolidated Analysis Centers Inc. and became a publicly traded company that provided IT services to the government and intelligence community. It is now called *CACI International*.

Markowitz's career has ranged across academia, research, and business. He worked in the money management industry as president of Arbitrage Management Company from 1969 to 1972. From 1974 until 1983, Markowitz was at IBM's T.J. Watson Research Center in Yorktown Heights, NY. He has taught at the University of California at Los Angeles, Baruch College and, since 1994, at the University of California at San Diego. He continues to teach at UC-San Diego and is an academic consultant to Index Fund Advisors, a financial services firm that provides low-cost index funds to investors.

In the fall of 2008 and subsequent winter, Markowitz's landmark portfolio theory came under harsh criticism in the lay press as all asset classes declined together. Markowitz, however, argued that the credit crisis and ensuing losses highlighted the benefits of diversification and exposed the risks in

not understanding, or in misunderstanding, the correlations between assets in a portfolio. “Portfolio theory was not invalidated, it was validated,” he noted in a 2009 interview with Index Fund Advisors [4]. He has said numerous times over the years that there are no “shortcuts” to understanding the trade-off between risk and return. “US portfolio theorists do not talk about risk control,” he said in that interview. “It sounds like you can control risk. You can’t.” “But diversification,” he continued, “is the next best thing.”

Merton, Robert C.

Robert C. Merton is the John and Natty McArthur University Professor at Harvard Business School. In 1966, he earned a BS in engineering mathematics from Columbia University where he published his first publication “The ‘Motionless’ Motion of Swift’s Flying Island” in the *Journal of the History of Ideas* [4]. He then went on to pursue graduate studies in applied mathematics at the California Institute of Technology, leaving the institution with an MS in 1967. He obtained a PhD in economics in 1970 from the Massachusetts Institute of Technology where he worked under the Nobel laureate Paul A. Samuelson (see **Samuelson, Paul A.**). His dissertation was entitled “Analytical Optimal Control Theory as Applied to Stochastic and Non-stochastic Economics.” Prior to joining Harvard in 1988, Merton served on the finance faculty of Massachusetts Institute of Technology.

In 1997, Merton shared the Nobel Prize in Economic Sciences with Myron Scholes “for a new method to determine the value of derivatives”. Merton taught himself stochastic dynamic programming and Ito calculus during graduate school at Massachusetts Institute of Technology and subsequently introduced Ito calculus (see **Stochastic Integrals**) into finance and economics. Continuous-time stochastic calculus had become a cornerstone in mathematical finance, and more than anyone Merton is responsible in making manifest the mathematical tool’s power in financial modeling and applications. Merton had also produced highly regarded work on dynamic models of optimal life-time consumption and portfolio selection, equilibrium asset pricing, contingent-claim analysis, and financial systems. Merton’s monograph “Continuous-time finance” [8] is a classic introduction to these topics.

Merton proposed an intertemporal capital asset pricing model (ICAPM) [6] (see **Capital Asset Pricing Model**), a model empirically more attractive than the single-period capital asset pricing model (CAPM) (see **Capital Asset Pricing Model**). Assuming continuous-time stochastic processes with continuous-decision-making and trading, Merton showed that mean–variance portfolio choice is optimal at each moment of time. It explained when and how the CAPM could hold in a dynamic setting. As an extension, Merton looked at the

case when the set of investment opportunities is stochastic and evolves over time. Investors hold a portfolio to hedge against shifts in the opportunity set of security returns. This implies that investors are compensated in the expected return for bearing the risk of shifts in the opportunity set of security returns, in addition to bearing market risk. Because of this additional compensation in expected return, in equilibrium, expected returns on risky assets may differ from the risk-less expected return even when they have no market risk. Through this work, we obtain an empirically more useful version of CAPM that allows for multiple risk factors. Merton’s ICAPM predated many subsequently published multifactor models like the arbitrage pricing theory [11] (see **Arbitrage Pricing Theory**).

Merton’s work in the 1970s laid the foundation for modern derivative pricing theory (see **Option Pricing: General Principles**). His paper “Theory of Rational Option Pricing” [5] is one of the two classic papers on derivative pricing that led to the Black–Scholes–Merton option pricing theory (see **Black–Scholes Formula**). Merton’s essential contribution was his hedging (see **Hedging**) argument for option pricing based on no arbitrage; he showed that one can use the prescribed dynamic trading strategy under Black–Scholes [1] to offset the risk exposure of an option and obtain a perfect hedge under the continuous trading limit. In other words, he discovered how to construct a “synthetic option” using continual revision of a “self-financing” portfolio involving the underlying asset and riskless borrowing to replicate the expiration-date payoff of the option. And no arbitrage dictates that the cost of constructing this synthetic option must give the price of the option even if it does not exist. This seminal paper also extended the Black–Scholes model to allow for predictably changing interest rates, dividend payments on the underlying asset, changing exercise price, and early exercise under American options. Merton also produced “perhaps the first closed-form formula for an exotic option”. [12] Merton’s approach to derivative securities provided the intellectual basis for the rise of the profession of financial engineering.

The Merton model (see **Structural Default Risk Models**) refers to an increasingly popular structural credit risk model introduced by Merton [7] in the early 1970s. Drawing on the insight that the payoff

structure of the leveraged equity of a firm is identical to that of a call option (*see Call Options*) on the market value of the assets of the whole firm, Merton proposed that the leveraged equity of a firm could be valued as if it were a call option on the assets of the whole firm. The isomorphic (same payoff structure) price relation between the leveraged equity of a firm and a call option allows one to apply the Black–Scholes–Merton contingent-claim pricing model to value the equities [7]. The value for the corporate debt could then be obtained by subtracting the value of the option-type structure that the leveraged equity represents from the total market value of the assets. Merton's methodology offered a way to obtain valuation functions for the equity and debt of a firm, a measure of the risk of the debt, as well as all the Greeks of contingent-claim pricing. The Merton model provided a useful basis for valuing and assessing corporate debt, its risk, and the sensitivity of debt value to various parameters (e.g., the delta gives the sensitivity of either debt value or equity value to change in asset value). Commercial versions of the Merton model include the KMV model and the Jarrow–Turnbull model.

Since the 1990s, Merton collaborated with Zvi Bodie, Professor of Finance at Boston University to develop a new line of research on the financial system [2, 9, 10]. They adopted a functional perspective, “similar in spirit to the functional approach in sociology pioneered by Robert K. Merton (1957)” [3, 9]. By focusing on the underlying functions of financial systems, the functional perspective takes functions rather than institutions and forms as the conceptual anchor in its analysis of financial institutional change over time and contemporaneous institutional differences across borders. The functional perspective is also useful for predicting and guiding financial institutional change. The existing approaches of neoclassical, institutional, and behavioral theories in economics are taken as complementary in the functional approach to understand financial systems.

Merton had made significant contributions to finance across a broad spectrum and they are too numerous to mention exhaustively. His other works include those on Markowitz–Sharpe-type models with investors with homogeneous beliefs but with incomplete information about securities, the use of

jump-diffusion models (*see Jump-diffusion Models*) in option pricing, valuation of market forecasts, pension reforms, and employee stock option (*see Employee Stock Options*).

In addition to his academic duties, Merton has also been partner of the now defunct hedge fund Long Term Capital Management (*see Long-Term Capital Management*) and is currently Chief Scientific Officer at the Trinsum Group.

Arbitrage: Historical Perspectives

The concept of arbitrage has acquired a precise, technical meaning in quantitative finance (see **Arbitrage Pricing Theory**; **Arbitrage Strategy**; **Arbitrage Bounds**). In theoretical pricing of derivative securities, an arbitrage is a riskless trading strategy that generates a positive profit with no net investment of funds. This definition can be loosened to allow the positive profit to be nonnegative, with no possible future state having a negative outcome and at least one state with a positive outcome. Pricing formulas for specific contingent claims are derived by assuming an absence of arbitrage opportunities. Generalizing this notion of arbitrage, the fundamental theorem of asset pricing provides that an absence of arbitrage opportunities implies the existence of an equivalent martingale measure (see **Fundamental Theorem of Asset Pricing**; **Equivalent Martingale Measures**). Combining absence of arbitrage with a linear model of asset returns, the arbitrage pricing theory decomposes the expected return of a financial asset into a linear function of various economic risk factors, including market indices. Sensitivity of expected return to changes in each factor is represented by a factor-specific beta coefficient. Significantly, while riskless arbitrage imposes restrictions on prices observed at a given point in time, the arbitrage pricing theory seeks to explain expected returns, which involve prices observed at different points in time.

In contrast to the technical definitions of arbitrage used in quantitative finance, colloquial usage of arbitrage in modern financial markets refers to a range of trading strategies, including municipal bond arbitrage; merger arbitrage; and convertible bond arbitrage. Correctly executed, these strategies involve trades that are low risk relative to the expected return but do have possible outcomes where profits can be negative. Similarly, uncovered interest arbitrage seeks to exploit differences between foreign and domestic interest rates leaving the risk of currency fluctuations unhedged. These notions of risky arbitrage can be contrasted with covered interest arbitrage, which corresponds to the definition of arbitrage used in quantitative finance of a riskless trading strategy that generates a positive profit with no net investment of funds. Cash-and-carry arbitrages related to

financial derivatives provide other examples of arbitrages relevant to the quantitative finance usage. Among the general public, confusion about the nature of arbitrage permitted Bernard Madoff to use the illusion of arbitrage profit opportunities to attract “hedge fund investments” into the gigantic Ponzi scheme that collapsed in late 2008. Tracing the historical roots of arbitrage trading provides some insight into the various definitions of arbitrage in modern usage.

Arbitrage in Ancient Times

Records about business practices in antiquity are scarce and incomplete. Available evidence is primarily from the Middle East and suggests that mercantile trade in ancient markets was extensive and provided a number of avenues for risky arbitrage. Potential opportunities were tempered by the lack of liquidity in markets; the difficulties of obtaining information and moving goods over distances; and, inherent political and economic risks. Trading institutions and available securities were relatively simple. Circa 1760 BC, the Code of Hammurabi dealt extensively with matters of trade and finance. Sumerian cuneiform tablets from that era indicate a rudimentary form of bill of exchange transaction was in use where a payment (disbursement) would be made in one location in the local unit of account, for example, barley, in exchange for disbursement (payment) at a later date in another location of an agreed upon amount of that local currency, for example, lead [6]. The date was typically determined by the accepted transport time between the locations. Two weeks to a month was a commonly observed time between the payment and repayment. The specific payment location was often a temple.

Ancient merchants developed novel and complex solutions to address the difficulties and risks in executing various arbitrage transactions. Because the two payments involved in the ancient bill of exchange were separated by distance and time, a network of agents, often bound together by family or tribal ties, was required to disburse and receive funds or goods in the different locations. Members of the caravan or ship transport were often involved in taking goods on consignment for sale in a different location where the cost of the goods would be repaid [6, p.15–6]. The merchant arbitrageur would offset the cost of purchasing goods given on consignment with payments from

other merchants seeking to avoid the risks of carrying significant sums of money over long distance, making a local payment in exchange for a disbursement of the local currency in a different location. The basic cash-and-carry arbitrage is complicated by the presence of different payment locations and currency units. The significant risk of delivery failure or nonpayment was controlled through the close-knit organizational structure of the merchant networks [7]. These same networks provided information on changing prices in different regions that could be used in geographical goods arbitrage.

The gradual introduction of standardized coinage starting around the 650 BC expanded available arbitrage opportunities to include geographical arbitrage of physical coins to exploit differing exchange ratios [6, p.19–20]. For example, during the era of the Athenian empire (480–404 BC), Persia maintained a bimetallic coinage system where silver was undervalued relative to gold. The resulting export of silver coins from Persia to Greece and elsewhere in the Mediterranean is an early instance of a type of arbitrage activity that became a mainstay of the arbitrageur in later years. This type of arbitrage trading was confined to money changers with the special skills and tools to measure the bullion value of coins. In addition to the costs and risks of transportation, the arbitrage was restricted by the seigniorage and minting charges levied in the different political jurisdictions. Because coinage was exchanged by weight and trading by bills of exchange was rudimentary, there were no arbitrageurs specializing solely in “arbitrating of exchange rates”. Rather, arbitrage opportunities arose from the trading activities of networks of merchants and money changers. These opportunities included uncovered interest arbitrage between areas with low interest rates, such as Jewish Palestine, and those with high rates, such as Babylonia [6, p.18–19].

Evolution of the Bill of Exchange

Though the precise origin of the practice is unknown, “arbitration of exchange” first developed during the Middle Ages. Around the time of the First Crusade, Genoa had emerged as a major sea power and important trading center. The Genoa fairs had become sufficiently important economic and financial events that attracted traders from around the Mediterranean.

To deal with the problems of reconciling transactions using different coinages and units of account, a forum for arbitrating exchange rates was introduced. On the third day of each fair, a representative body composed of recognized merchant bankers would assemble and determine the exchange rates that would prevail for that fair. The process involved each banker suggesting an exchange rate and, after some discussion, a voting process would determine the exchange rates that would apply at that fair. Similar practices were adopted at other important fairs later in the Middle Ages. At Lyon, for example, Florentine, Genoese, and Lucca bankers would meet separately to determine rates, with the average of these group rates becoming the official rate. These rates would then apply to bill transactions and other business conducted at the fair. Rates typically stayed constant between fairs in a particular location providing the opportunity for arbitrage of exchange rates across fairs in different locations.

From ancient beginnings involving commodity transactions of merchants, the bill of exchange evolved during the Middle Ages to address the difficulties of using specie or bullion to conduct foreign exchange transactions in different geographical locations. In general, a bill of exchange contract involved four persons and two payments. The bill is created when a “deliverer” exchanges domestic cash money for a bill issued by a “taker”. The issued bill of exchange is drawn on a correspondent or agent of the taker who is situated abroad. The correspondent, the “payer”, is required to pay a stated amount of foreign cash money to the “payee”, to whom the bill is made payable. Consider the precise text of an actual bill of exchange from the early seventeenth century that appeared just prior to the introduction of negotiability [28, p.123]:

March 14, 1611

In London for £69.15.7 at 33.9

At half usance pay by this first of exchange to Francesco Rois Serra sixty-nine pounds, fifteen shillings, and seven pence sterling at thirty-three shillings and nine pence groat per £ sterling, value [received] from Master Francesco Pinto de Britto, and put it into our account, God be with you.

Giovanni Calandrini and
Filippo Burlamachi

Accepted

[On the back:] To Balthasar Andrea in Antwerp
First 117.15.0 [pounds groat]

The essential features of the bill of exchange all appear here: the four separate parties; the final payment being made in a different location from the original payment; and the element of currency exchange. “Usance” is the period of time, set by custom, before a bill of exchange could be redeemed at its destination. For example, usance was 3 months between Italy and London and 4 weeks between Holland and London. The practice of issuing bills at usance, as opposed to specifying any number of days to maturity, did not disappear until the nineteenth century [34, p.7].

Commercial and financial activities in the Middle Ages were profoundly impacted by Church doctrine and arbitrage trading was no exception. Exchange rates determined for a given fair would have to be roughly consistent with triangular arbitrage to avoid Church sanctions. In addition, the Church usury prohibition impacted the payment of interest on money loans. Because foreign exchange transactions were licit under canon law, it was possible to disguise the payment of interest in a combination of bill of exchange transactions referred to as *dry exchange* or *fictitious exchange* [13, p.380–381], [17, 26]. The associated exchange and re-exchange of bills was a risky set of transactions that could be covertly used to invest money balances or to borrow funds to finance the contractual obligations. The expansion of bill trading for financial purposes combined with the variation in the exchange rates obtained at fairs in different locations provided the opportunity of geographical arbitrage of exchange rates using bills of exchange. It was this financial practice of exploiting differences in bill exchange rates between financial centers that evolved into the “arbitration of exchange” identified by la Porte [22], Savary [24], and Postelwayte [30] in the eighteenth century.

The bill of exchange contract evolved over time to meet the requirements of merchant bankers. As monetary units became based on coinage with specific bullion content, the relationship between exchange rates in different geographical locations for bills of exchange, coinage, and physical bullion became the mainstay of traders involved in “arbitration of exchange”. Until the development of the “inland” bill in early seventeenth century in England, all bills of exchange involved some form of foreign exchange trading, and hence the name *bill of exchange*. Contractual features of the bill of exchange, such as negotiability and priority of claim, evolved over time

producing a number of different contractual variations [9, 15, 26]. The market for bills of exchange also went through a number of different stages. At the largest and most strategic medieval fairs, financial activities, especially settlement and creation of bills of exchange, came to dominate the trading in goods [27]. By the sixteenth century, bourses such as the Antwerp Exchange were replacing the fairs as the key international venues for bill trading.

Arbitrage in Coinage and Bullion

Arbitrage trading in coins and bullion can be traced to ancient times. Reflecting the importance of the activity to ordinary merchants in the Middle Ages, methods of determining the bullion content of coins from assay results, and rates of exchange between coins once bullion content had been determined, formed a substantial part of important commercial arithmetics, such as the *Triparty* (1484) of Nicolas Chuquet [2]. The complications involved in trading without a standardized unit of account were imposing. There were a sizable number of political jurisdictions that minted coins, each with distinct characteristics and weights [14]. Different metals and combinations of metals were used to mint coinage. The value of silver coins, the type of coins most commonly used for ordinary transactions, was constantly changing because of debasement and “clipping”. Over time, significant changes in the relative supply of gold and silver, especially due to inflows from the New World, altered the relative values of bullion. As a result, merchants in a particular political jurisdiction were reluctant to accept foreign coinage at the par value set by the originating jurisdiction. It was common practice for foreign coinage to be assayed and a value set by the mint conducting the assay. Over time, this led to considerable market pressures to develop a unit of account that would alleviate the expensive and time-consuming practice of determining coinage value.

An important step in the development of such a standardized unit of account occurred in 1284 when the Doge of Venice began minting the gold ducat: a coin weighing about 3.5 g and struck in 0.986 gold. While ducats did circulate, the primary function was as a trade coin. Over time, the ducat was adopted as a standard for gold coins in other countries, including other Italian city states, Spain,

Austria, the German city states, France, Switzerland, and England. Holland first issued a ducat in 1487 and, as a consequence of the global trading power of Holland in the sixteenth and seventeenth centuries, the ducat became the primary trade coin for the world. Unlike similar coins such as the florin and guinea, the ducat specifications of about 3.5 g of 0.986 gold did not change over time. The use of mint parities for specific coins and market prices for others did result in the gold–silver exchange ratio differing across jurisdictions. For example, in 1688, the Amsterdam gold–silver ratio for the silver rixdollar mint price and gold ducat market price was 14.93 and, in London, the mint price ratio was 15.58 for the silver shilling and gold guinea [25, p.475]. Given transport and other costs of moving bullion, such gold/silver price ratio differences were not usually sufficient to generate significant bullion flows. However, combined in trading with bills of exchange, substantial bullion flows did occur from arbitrage trading.

Details of a May 1686 arbitrage by a London goldsmith involving bills of exchange and gold coins are provided by Quinn [25, p.479]. The arbitrage illustrates how the markets for gold, silver, and bills of exchange interacted. At that time, silver was the primary monetary metal used for transactions though gold coins were available. Prior to 1663, when the English Mint introduced milling of coins with serrated edges to prevent clipping, all English coins were “hammered” [20]. The minting technology of hammering coins was little changed from Roman times. The process produced imperfect coins, not milled at the edges, which were only approximately equal in size, weight, and imprint making altered coins difficult to identify [29, ch.4]. Such coins were susceptible to clipping, resulting in circulating silver coins that were usually under the nominal Mint weight. Despite a number of legislative attempts at remedying the situation, around 1686, the bulk of the circulating coins in England were still hammered silver. The Mint would buy silver and gold by weight in exchange for milled silver shilling coins at a set price per ounce. When the market price of silver rose sufficiently above the mint price, English goldsmiths would melt the milled silver coin issued by the Mint, though it was technically illegal to do so.

In addition to mint prices for silver and gold, there were also market prices for gold and silver. Around 1686, the Mint would issue guineas in exchange

for silver shillings at a fixed price (£1.075 = 21s. 6d./oz.). In Amsterdam, the market price for a Dutch gold ducat was 17.5 schellingen (*S*). Observing that the ducat contained 0.1091 ounces of recoverable gold and the guinea 0.2471 ounces, it follows that 36.87 *S* could be obtained for £1 if gold was used to effect the exchange. Or, put differently, 1 ducat would produce £0.4746. Because transportation of coins and bullion was expensive, there was a sizable band within which rates on bills of exchange could fluctuate without producing bullion flows. If the (*S*/£) bill exchange rate rose above the rate of exchange for gold plus transport costs, merchants in Amsterdam seeking funds in London would prefer to send gold rather than buy bills of exchange on London. Merchants in London seeking funds in Amsterdam would buy bills on Amsterdam to benefit from the favorable exchange. Similarly, if the bill exchange rate fell below the rate of exchange for silver plus transport costs, merchants in London would gain by exporting silver to Amsterdam rather than buying a bill on Amsterdam.

To reconstruct the 1686 goldsmith arbitrage, observe that the exchange rate for a 4-week bill in London on Amsterdam at the time of the arbitrage was 37.8 (*S*/£). Obtaining gold ducats in Holland for £0.4746 and allowing for transport costs of 1.5% and transport time of 1 week produces gold in London for £0.4676. Using this gold to purchase a bill of exchange on Amsterdam produces 17.6715 *S* in Amsterdam 5 weeks after the trade is initiated, an arbitrage profit of 0.1715 *S*. Even if the gold can be borrowed in Amsterdam and repaid in silver, the trade is not riskless owing to the transport risk and the possible movement in bill rates before the bill is purchased in London. These costs would be mitigated significantly for a London firm also operating in the bill and bullion market of Amsterdam, as was the case with a number of London goldsmiths. The strength of the pound sterling in the bill market from 1685–1688 generated gold inflows to England from this trade higher than any other four-year period in the seventeenth century [25, p.478]. The subsequent weakening of the pound in the bill market from 1689 until the great recoinage in 1696 led to arbitrage trades switching from producing gold inflows to substantial outflows of silver from melted coins and clipping.

Bill of Exchange Arbitrage

The roots of “arbitration of exchange” can be traced to the transactions of medieval merchant bankers seeking to profit from discrepancies in bill exchange rates across geographical locations [27, 28]. For example, if sterling bills on London were cheaper in Paris than in Bruges, then medieval bankers would profit by selling sterling in Bruges and buying in Paris. The effect of such transactions was to keep all exchange rates roughly in parity with the triangular arbitrage condition. Temporary discrepancies did occur but such trading provided a mechanism of adjustment. The arbitrages were risky even when done entirely with bills of exchange. Owing to the slowness of communications, market conditions could change before bills of exchange reached their destination and the re-exchange could be completed. As late as the sixteenth century, only the Italian merchant bankers, the Fuggers of Augsburg, and a few other houses with correspondents in all banking centers were able to engage actively in arbitrage [28, p.137]. It is not until the eighteenth century that markets for bills were sufficiently developed to permit arbitration of exchange to become standard practice of merchants deciding on the most profitable method of remitting or drawing funds offshore.

The transactions in arbitration of exchange by medieval bankers are complicated by the absence of offsetting cash flows in the locations where bills are bought and sold. In the example above, the purchase of a bill in Paris would require funds, which are generated by the bill sale in Bruges. The profits are realized in London. Merchant bankers would be able to temporarily mitigate the associated geographical fund imbalances with internally generated capital, but re-exchanges or movements of bullion were necessary if imbalances persisted. To be consistent with the spirit of the self-financing element of modern riskless arbitrage, the example of medieval banker arbitrage among Paris, Bruges, and London can be extended to two issuing locations and two payment centers. It is possible for the same location to be used as both the issuing and payment location but that will not be assumed. Let the two issuing locations be, say, Antwerp and Hamburg, with the two payment locations being London and Venice. The basic strategy involves making offsetting bill transactions in the two issuing locations

and then matching the settlements in the payment centers.

In the following example, $\$G$ is the domestic currency in Hamburg and $\$A$ is the domestic currency in Antwerp, the forward exchange rate imbedded in the bill transaction is denoted as F_1 for Ducats/ $\$A$; F_2 for Ducats/ $\$G$; F_3 for $\pounds/\$G$; and, F_4 for $\pounds/\$A$.

In Hamburg

Acquire $\$G Q_G$ using a bill which agrees to pay ($\$G Q_G F_2$) in Venice at time T	Deliver the $\$G Q_G$ on another bill which agrees to be repaid ($\$G Q_G F_3$) in London at time T
--	---

In Antwerp

Acquire $\$A Q_A$ using a bill which agrees to pay ($\$A Q_A F_4$) in London at time T	Deliver the $\$A Q_A$ on another bill which agrees to be repaid ($\$A Q_A F_1$) in Venice at time T
--	---

At $t = 0$, the cash flows from all the bill transactions at $t = 0$ offset. If the size of the borrowings in the two issuing centers is calculated to produce the same maturity value, in terms of the domestic currencies of the two payment centers, then the profit on the transaction depends on the relative values of the payment center currencies in the issuing centers. If there is sufficient liquidity in the Hamburg and Antwerp bill markets, the banker can generate triangular arbitrage trades designed to profit from discrepancies in bid/offer rates arising in different geographical locations.

To see the precise connection to triangular arbitrage, consider the profit function from the trading strategy. At time T in Venice, the cash flows would provide $(\$A Q_A F_1) - (\$G Q_G F_2)$. And, in London, the cash flows would provide $(\$G Q_G F_3) - (\$A Q_A F_4)$. For the intermediary operating in both locations, the resulting profit (π) on the trade would be the sum of the two cash flows:

$$\begin{aligned}
 \pi(T) &= (\$A Q_A F_1 - \$G Q_G F_2) \\
 &\quad + (\$G Q_G F_3 - \$A Q_A F_4) \\
 &= \$A Q_A (F_1 - F_4) + \$G Q_G (F_3 - F_2)
 \end{aligned} \tag{1}$$

Constructing the principal values of the two transactions to be of equal value now permits the substitution of $Q_G = Q_A (\$G/\$A)$, where $(\$G/\$A) = F_0$ is the prevailing exchange rate between $\$G$ and $\$A$:

$$\begin{aligned}\pi(T) &= \$A Q_A [(F_1 - F_0 F_2) - (F_4 - F_0 F_3)] \\ &= \$A Q_A \left[\left(\frac{\text{Ducats}}{\$A} - \frac{\$G \text{ Ducats}}{\$A G} \right) \right. \\ &\quad \left. - \left(\frac{\pounds}{\$A} - \frac{\$G \pounds}{\$A \$G} \right) \right] \quad (2)\end{aligned}$$

The two values in brackets will be zero if triangular arbitrage holds for both currencies. If the direct and indirect exchange rates for one of the currencies are not consistent with triangular arbitrage, then the banker can obtain a self-financing arbitrage profit.

Arbitration of Exchange

By the eighteenth century, the bill market in key financial centers such as Amsterdam, London, Hamburg, and Paris had developed to the point where merchants as well as bankers could engage in arbitration of exchange to determine the most profitable method of remitting funds to or drawing funds from offshore locations. From a relatively brief treatment in early seventeenth century sources, for example, [13], merchants' manuals detailing technical aspects of bill trading were available by the beginning of the eighteenth century. The English work by Justice, *A General Treatise on Money and Exchanges* [9], an expanded translation of an earlier treatise in French by M. Ricard, details the workings of bill transactions, recognizing subtle characteristics in the bill contract. However, as a reflection of the rudimentary state of the English bill market in the early eighteenth century, Justice did not approve of "drawing bills upon one country payable in another" due to the "difference in the Laws of Exchange, in different countries" giving rise to "a great many inconveniences" [9, p.28]. As the eighteenth century progressed, there was substantial growth in the breadth and depth of the bill market supported by increases in speed of communication between key financial centers with London emerging as the focal point [16, 31]. This progress was reflected in the increasingly sophisticated treatment of arbitration of exchange in merchants' manuals.

Merchants' manuals of the eighteenth and nineteenth centuries typically present arbitration of exchange from the perspective of a merchant engaged in transferring funds. In some sources, self-financing arbitrage opportunities created by combining remitting and drawing opportunities are identified. Discussions of the practice invariably involve calculations of the "arbitrated rates". Earlier manuals such as the one by Le Moine [11] only provide a few basic calculations aimed to illustrate the transactions involved. The expanded treatment in Postlewayt [24] provides a number of worked calculations. In one example, exchange rates at London are given as London–Paris 31 3/4 pence sterling for 1 French crown; London–Amsterdam as 240 pence sterling for 414 groats. Worked calculations are given for the problem "What is the proportional arbitrated price between Amsterdam and Paris?" Considerable effort is given to show the arithmetic involved in determining this arbitrated rate as 54 123/160 groat for 1 crown. Using this calculated arbitrated exchange rate and the already known actual London–Paris rate, Postlewayt then proceeds to determine the arbitrated rate for London–Amsterdam using these exchange rates for Paris–London and Paris–Amsterdam finding that it equals 240 pence sterling for 414 groats.

Having shown how to determine arbitrated rates, Postlewayt provides worked examples of appropriate arbitrage trades when the actual exchange rate is above or below the arbitrated rate. For example, when the arbitrated Amsterdam–Paris rate is above the actual rate, calculations are provided to demonstrate that drawing sterling in London by selling a bill on Paris, using the funds to buy a bill on Amsterdam and then exchanging the guilders/groats received in Amsterdam at the actual rate to cover the crown liability in Paris will produce a self-financing arbitrage profit. Similarly, when the arbitrated Amsterdam–Paris rate is below the actual rate, the trades in the arbitrage involve drawing sterling in London by selling a bill on Amsterdam, using the funds to buy a bill on Paris and then exchanging at the actual Amsterdam–Paris exchange rate the crowns received in Paris to cover the guilder liability. This is similar to the risky medieval banker arbitrage where the rate on re-exchange is uncertain. Though the actual rate is assumed to be known, in practice, this rate could change over the time period it takes to settle the relevant bill transactions. However, the degree of risk

facing the medieval banker was mitigated by the 18th century due to the considerably increased speed of communication between centers and subsequent developments in the bill contract, such as negotiability and priority of claim.

Earlier writers on arbitration of exchange, such as Postlewayt, accurately portrayed the concept but did not adequately detail all costs involved in the transactions. By the nineteenth century, merchants' manuals such as [34] accurately described the range of adjustments required for the actual execution of the trades. Taking the perspective of a London merchant with sterling seeking to create a fund of francs in Paris, a difference is recognized between two methods of determining the direct rate of exchange: buying a bill in the London market for payment in Paris; or having correspondents in Paris issue for francs a bill for sterling payment in London. In comparing with the arbitrated rates, the more advantageous direct rate is used. In determining direct rates, 3-month bill exchange rates are used even though the trade is of shorter duration. These rates are then adjusted to "short" rates to account for the interest factor. Arbitrated rates are calculated and, in comparing with direct rates, an additional brokerage charge (plus postage) is deducted from the indirect trade due to the extra transaction involved, for example, a London merchant buys a bill for payment in Frankfurt, which is then sold in Paris. No commissions are charged as it is assumed that the trade is done "between branches of the same house, or on joint account" [34, p.98].

Arbitrage in Securities and Commodities

Arbitrage involving bills of exchange survives in modern times in the foreign exchange swap trades of international banks. Though this arbitrage is of central historical importance, it attracts less attention now than a range of arbitrage activities involving securities and commodities that benefited from the financial and derivative security market developments of the nineteenth century. Interexchange and geographical arbitrages were facilitated by developments in communication. The invention of the telegraph in 1844 permitted geographical arbitrage in stocks and shares between London and the provincial stock exchanges by the 1850s. This trade was referred to as *shunting*. In 1866, Europe and America were linked by cable, significantly enhancing the

speed at which price discrepancies across international markets could be identified. Telegraph technology allowed the introduction of the stock market ticker in 1867. Opportunity for arbitrating differences in the prices of securities across markets was further aided by expansion of the number and variety of stocks and shares, many of which were interlisted on different regional and international exchanges. (Where applicable, the nineteenth century convention of referring to fixed-income securities as *stocks* and common stocks as *shares* will be used.) For example, after 1873 arbitrating the share price of Rio Tinto between the London and Paris stock exchanges was a popular trade.

Cohn [3, p.3] attributes "the enormous increase in business on the London Stock Exchange within the last few years" to the development of "Arbitrage transactions between London and Continental Bourses". In addition to various government bond issues, available securities liquid enough for arbitrage trading included numerous railway securities that appeared around the middle of the century. For example, both Haupt [8] and Cohn [3] specifically identify over a dozen securities traded in Amsterdam that were sufficiently liquid to be available for arbitrage with London. Included on both lists are securities as diverse as the Illinois and Erie Railway shares and the Austrian government silver loan. Securities of mines and banks increased in importance as the century progressed. The expansion in railway securities, particularly during the US consolidations of the 1860s, led to the introduction of traded contingencies associated with these securities such as rights issues, warrant options, and convertible securities. Weinstein [33] identifies this development as the beginning of arbitrage in equivalent securities, which, in modern times, encompasses convertible bond arbitrage and municipal bond arbitrage. However, early eighteenth century English and French subscription shares do have a similar claim [32]. Increased liquidity in the share market provided increased opportunities for option trading in stocks and shares.

Also during the nineteenth century, trading in "time bargains" evolved with the commencement of trading in such contracts for agricultural commodities on the Chicago Board of Trade in 1851. While initially structured as forward contracts, adoption of the General Rules of the Board of Trade in 1865 laid a foundation for trading of modern

futures contracts. Securities and contracts with contingencies have a history stretching to ancient times when trading was often done using samples and merchandise contracts had to allow for time to delivery and the possibility that the sample was not representative of the delivered goods. Such contingencies were embedded in merchandise contracts and were not suited to arbitrage trading. The securitization of such contingencies into forward contracts that are adaptable to cash-and-carry arbitrage trading can be traced to the introduction of “to arrive” contracts on the Antwerp bourse during the sixteenth century [19, ch.9]. Options trading was a natural development on the trade in time bargains, where buyers could either take delivery or could pay a fixed fee in lieu of delivery. In effect, such forward contracts were bundled with an option contract having the premium paid at delivery.

Unlike arbitration of exchange using bills of exchange, which was widely used and understood by the eighteenth century, arbitrage trades involving options—also known as *privileges* and *premiums*—were not. Available sources on such trades conducted in Amsterdam, Joseph de la Vega [21, ch.3] and Isaac da Pinto [19, p.366–377] were written by observers who were not the actual traders, so only crude details of the arbitrage trades are provided. Conversion arbitrages for put and call options, which involves knowledge of put–call parity, are described by both de la Vega and da Pinto. Despite this, prior to the mid-nineteenth century, options trading was a relatively esoteric activity confined to a specialized group of traders. Having attracted passing mention by Cohn [3], Castelli [1, p.2] identifies “the great want of a popular treatise” on options as the reason for undertaking a detailed treatment of mostly speculative option trading strategies. In a brief treatment, Castelli uses put–call parity in an arbitrage trade combining a short position in “Turks 5%” in Constantinople with a written put and purchased call in London. The trade is executed to take advantage of “enormous contangoes collected at Constantinople” [1, p.74–77].

Etymology and Historical Usage

The Oxford International Dictionary [12] defines arbitrage as: “the traffic in bills of exchange drawn on sundry places, and bought or sold in sight of the

daily quotations of rates in several markets. Also, the similar traffic in stock.” The initial usage is given as 1881. Reference is also directed to “arbitration of exchange” where the definition is “the determination of the rate of exchange to be obtained between two countries or currencies, when the operation is conducted through a third or several intermediate ones, in order to ascertain the most advantageous method of drawing or remitting bills.” The singular position given to “arbitration of exchange” trading using bills of exchange recognizes the practical importance of these securities in arbitrage activities up to that time. The Oxford International Dictionary definition does not recognize the specific concepts of arbitrage, such as triangular currency arbitrage or interexchange arbitrage, or that such arbitrage trading applies to coinage, bullion, commodities, and shares as well as to trading bills of exchange. There is also no recognition that doing arbitrage with bills of exchange introduces two additional elements not relevant to triangular arbitrage for manual foreign exchange transactions: time and location.

The word “arbitrage” is derived from a Latin root (*arbitrari*, to give judgment; *arbitrio*, arbitration) with variants appearing in the Romance languages. Consider the modern Italian variants: *arbitraggio* is the term for arbitrage; *arbitrato* is arbitration or umpiring; and, *arbitrarer* is to arbitrate. Similarly, for modern French variants, *arbitrage* is arbitration; *arbitrer* is to arbitrate a quarrel or to umpire; and *arbitre* is an arbitrator or umpire. Recognizing that the “arbitration of prices” concept underlying arbitrage predates Roman times, the historical origin where the word arbitrage or a close variant was first used in relation to arbitrating differences in prices is unknown. A possible candidate involves arbitration of exchange rates for different currencies observed at the medieval fairs, around the time of the First Crusade (1100). The dominance of Italian bankers in this era indicates the first usage was the close variant, *arbitrio*, with the French “*arbitrage*” coming into usage during the eighteenth century. Religious and social restrictions effectively barred public discussion of the execution and profitability of such banking activities during the Middle Ages, though account books of the merchant banks do remain as evidence that there was significant arbitrage trading.

As late as the seventeenth century, important English sources on the Law Merchant such as Gerard Malynes, *Lex Mercatoria* [13], make no reference to arbitrage trading strategies in bills of exchange. In contrast, a similar text in Italian, *Il Negotiante* (1638) by Giovanni Peri [18], a seventeenth century Italian merchant, has a detailed discussion on exchange dealings. Peri states that profit is the objective of all trade and that the “activity directed to this end is subject to chance, which mocks at every calculation. Yet there is still ample space for reasonable calculation in which the possibility of adverse fortunes is never left out of account” [5, p.327]. This mental activity engaged in the service of business is called *arbitrio*. Peri identifies a connection between speculation on future exchange rate movements and the *arbitrio* concept of arbitrage: “the profits from exchange dealings originate in price differences and not in time” with profits turning to losses if re-exchange is unfavorable [18, p.150]. For Peri, the connection between speculation and arbitrage applies to commodities and specie, as well as bills of exchange.

The first published usage of “arbitrage” in discussing the relationship between exchange rates and the most profitable locations for issuing and settling a bill of exchange appears in French in, *La Science des Négocians et Teneurs de Livres* [22, p.452]. From the brief reference in a glossary of terms by de la Porte, a number of French sources, including the section *Traité des arbitrages* by Mondoteguy in Le Moine, *Le Negoce d'Amsterdam* [11] and Savary, *Dictionnaire Universel de Commerce* (1730, 2nd ed.) [30], developed a more detailed presentation of arbitrage transactions involving bills of exchange. An important eighteenth century English source, *The Universal Dictionary of Trade and Commerce* [24], is an expanded translation of Savary where the French word “arbitrage” is translated into English as “arbitration”. This is consistent with the linguistic convention of referring to arbitration instead of arbitrage found in the earlier English source, *The Merchant's Public Counting House* [23]. This led to the common English use of the terms “simple arbitrations”, “compound arbitrations”, and “arbitrated rates”. The practice of using arbitration instead of arbitrage continues into nineteenth century works by Patrick Kelly, *The Universal Cambist* [10] and William Tate, *The Modern Cambist* [34]. The latter book went into six editions.

Following the usage of “arbitrage” in German and Dutch works in the 1860s, common usage of “arbitrageur” in English appears with Ottomar Haupt, *The London Arbitrageur* [8], though reference is still made to “arbitration of exchange” as the activity of the arbitrageur. Haupt produced similar works in German and French that used “arbitrage” to describe the calculation of parity relationships. A pamphlet by Maurice Cohn, *The Stock Exchange Arbitrageur* [3] describes “arbitrage transactions” between bourses but also uses “arbitration” to refer to calculated parity relationships. Charles Castelli's *The Theory of “Options” in Stocks and Shares* [1] concludes with a section on “combination of options with arbitrage operations” where arbitrage has exclusive use and no mention is made of “arbitration” of prices or rates across different locations. Following *Arbitrage in Bullion, Coins, Bills, Stocks, Shares and Options* by Henry Deutsch [4], “arbitration of exchange” is no longer commonly used.

GEOFFREY POITRAS

Utility Theory: Historical Perspectives

The first recorded mention of a concave utility function in the context of risk and uncertainty is in a manuscript of Daniel Bernoulli [4] in 1738, though credit should also be given to Gabriel Cramer, who, according to Bernoulli himself, developed a remarkably similar theory in 1728. Bernoulli proposes a resolution of a paradox posed in 1713 by his cousin Nicholas Bernoulli. Known as the *St. Petersburg paradox*, it challenges the idea that rational agents value random outcomes by their expected returns. Specifically, a game is envisioned in which a fair coin is tossed repeatedly and the payoff equals 2^n ducats if the first *heads* appeared on the n th toss. The expected value of the payoff can be computed as

$$\begin{aligned} \frac{1}{2} \times 2 + \frac{1}{4} \times 4 + \frac{1}{8} \times 8 + \cdots \\ + \frac{1}{2^n} \times 2^n + \cdots = +\infty \end{aligned} \quad (1)$$

but, clearly, no one would pay an infinite, or even a large finite, amount of money for a chance to play such a game. Daniel Bernoulli suggests that the *satisfaction* or *utility* $U(w)$ from a payoff of size w should not be proportional to w (as mandated by the then prevailing valuation by expectation), but should exhibit diminishing marginal returns; in contemporary language, the derivative U' of the function U should be decreasing (*see Utility Function*). Proposing a logarithmic function as a suitable U , Bernoulli suggests that the *value* of the game to the agent should be calculated as the expected utility

$$\begin{aligned} \frac{1}{2} \times \log(2) + \frac{1}{4} \times \log(4) + \frac{1}{8} \times \log(8) + \cdots \\ + \frac{1}{2^n} \times \log(2^n) + \cdots = \log(4) \end{aligned} \quad (2)$$

Bernoulli's theory was poorly accepted by his contemporaries. It was only a hundred years later that Herman Gossen [11] used Bernoulli's idea of diminishing marginal utility of wealth to formulate his "Laws of Economic Activity". Gossen's "Second law"—the idea that the ratio of exchange values of two goods must equal the ratio of marginal utilities

of the traders—presaged, but did not directly influence, what will become known in economics as the "Marginalist revolution" led by William Jevons [13], Carl Menger [17], and Leon Walras [26].

Axiomatization

The work of Gossen notwithstanding, another century passed before the scientific community took an interest in Bernoulli's ideas (with some notable exceptions such as Alfred Marshall [16] or Francis Edgeworth's entry on probability [8] in the celebrated 1911 edition of *Encyclopedia Britannica*). In 1936, Franz Alt published the first axiomatic treatment of decision making in which he deduces the existence of an implied utility function solely on the basis of a simple set of plausible axioms. Eight years later, Oskar Morgenstern and John von Neumann published the widely influential "Theory of Games and Economic Behavior" [25]. Along with other contributions—the most important representative being a mathematically rigorous foundation of game theory—they develop, at great length, a theory similar to Alt's. Both Alt's and the von Neumann–Morgenstern axiomatizations study a preference relation on the collection of all lotteries (probability distributions on finite sets of outcomes) and show that one lottery is preferred to the other if and only if the expected utility of the former is larger than the expected utility of the latter. The major conceptual leap accomplished by Alt, von Neumann, and Morgenstern was to show that the *behavior* of a rational agent necessarily coincides with the behavior of an agent who values uncertain payoffs using an expected utility.

The Subjectivist Revolution and the State-preference Approach

All of the aforementioned derivations of the expected-utility hypothesis assumed the existence of a physical (objective) probability over the set of possible outcomes of the random payoff. An approach in which both the probability distribution and the utility function are determined jointly from simple behavioral axioms has been proposed by Leonard Savage [23], who was inspired by the work of Frank Ramsey [21] and Bruno de Finetti [5, 6].

One of the major features of the expected-utility theory is the separation between the utility function and the resolution of uncertainty, in that equal payoffs in different states of the world yield the same utilities. It has been argued that, while sometimes useful, such a separation is not necessary. An approach in which the utility of a payoff depends not only on its monetary value but also on the state of the world has been proposed. Such an approach has been popularized through the work of Kenneth Arrow [2] (see **Arrow, Kenneth**) and Gerard Debreu [7], largely because of its versatility and compatibility with general-equilibrium theory where the payoffs are not necessarily monetary. Further successful applications have been made by Roy Radner [20] and many others.

Empirical Paradoxes and Prospect Theory

With the early statistical evidence being mostly anecdotal, many empirical studies have found significant inconsistencies between the observed behavior and the axioms of utility theory. The most influential of these early studies were performed by George Shackle [24], Maurice Allais [1], and Daniel Ellsberg [9]. In 1979, Daniel Kahneman and Amos Tversky [14] proposed “prospect theory” as a psychologically more plausible alternative to the expected utility theory.

Utility in Financial Theory

The general notion of a numerical value associated with a risky payoff was introduced to finance by Harry Markowitz [15] (see **Markowitz, Harry**) through his influential “portfolio theory”.

Markowitz’s work made transparent the need for a precise measurement and quantitative understanding of the levels of “risk aversion” (degree of concavity of the utility function) in financial theory. Even though a similar concept had been studied by Milton Friedman and Leonard Savage [10] before that, the major contribution to this endeavor was made by John Pratt [19] and Kenneth Arrow [3].

With the advent of stochastic calculus (developed by Kiyosi Itô [12], see **Itô, Kiyosi (1915–2008)**), the mathematical tools for continuous-time financial modeling became available. Paul Samuelson [22] (see **Samuelson, Paul A.**) introduced geometric

Brownian motion as a model for stock evolution, and it was not long before it was combined with expected utility theory in the work of Robert Merton [18] (see **Merton, Robert C.**).

GORDAN ŽITKOVIĆ

Itô, Kiyosi (1915–2008)

Kiyosi Itô was born in 1915, approximately 60 years after the Meiji Restoration. Responding to the appearance of the “Black Ships” in Yokohama harbor and Commodore Perry’s demand that they open their doors, the Japanese overthrew the Tokugawa shogunate and in 1868 “restored” the emperor Meiji to power. The Meiji Restoration initiated a period of rapid change during which Japan made a concerted and remarkably successful effort to transform itself from an isolated, feudal society into a modern state that was ready to play a major role in the world.

During the first phase of this period, they sent their best and brightest abroad to acquire and bring back to Japan the ideas and techniques that had been previously blocked entry by the shogunate’s closed door policy. However, by 1935, the year that Itô entered Tokyo University, the Japanese transformation process had already moved to a second phase, one in which the best and brightest were kept at home to study, assimilate, and eventually disseminate the vast store of information which had been imported during the first phase. Thus, Itô and his peers were expected to choose a topic that they would first teach themselves and then teach their compatriots. For those of us who had the benefit of step-by-step guidance from knowledgeable teachers, it is difficult to imagine how Itô and his fellow students managed, and we can only marvel at the fact that they did.

The topic which Itô chose was that of stochastic processes. At the time, the field of stochastic processes had only recently emerged and was still in its infancy. N. Wiener (1923) had constructed Brownian motion, A.N. Kolmogorov (1933) and Wm. Feller (1936) had laid the analytic foundations on which the theory of diffusions would be built, and P. Lévy (1937) had given a pathspace interpretation of infinitely divisible laws. However, in comparison to well-established fields such as complex analysis, stochastic processes still looked more like a haphazard collection of examples than a unified field.

Having studied mechanics, Itô from the outset was drawn to Lévy’s pathspace perspective with its emphasis on paths and dynamics, and he set as his goal the reconciliation of Kolmogorov and Feller’s analytic treatment with Lévy’s pathspace picture. To carry out his program, he first had to thoroughly

understand Lévy, and, as anyone who has attempted to read Lévy in the original knows, this in itself a daunting task. Indeed, I have my doubts that, even now, many of us would know what Lévy did had Itô not explained it to us. Be that as it may, Itô’s first published paper (1941) was devoted to a reworking (incorporating important ideas due to J.L. Doob) of Lévy’s theory of homogeneous, independent increment processes.

Undoubtedly as a dividend of the time and effort which he spent unraveling Lévy’s ideas, shortly after completing this paper Itô had a wonderful insight of his own. To explain his insight, imagine that the space $M_1(\mathbb{R})$ of probability measures on $\mathbb{R}$ has a differentiable structure in which the underlying dynamics is given by convolution. Then, if $t \in [0, \infty) \mapsto \mu_t \in M_1(\mathbb{R})$ is a “smooth curve” which starts at the unit point mass δ_0 , its “tangent” at time 0, it should be given by the limit

$$\lim_{n \rightarrow \infty} \left(\mu \frac{1}{n} \right)^{\star n}$$

where $\star$ denotes convolution and therefore $\nu^{\star n}$ is the n -fold convolution power of $\nu \in M_1(\mathbb{R})$. What Itô realized is that, if this limit exists, it must be an infinitely divisible law. Applied to $\mu_t = P(t, x, \cdot)$, where $(t, x) \in [0, \infty) \times \mathbb{R} \mapsto P(t, x, \cdot) \in M_1(\mathbb{R})$ is the transition probability function for a Markov process, this key observation lead Itô to view Kolmogorov’s forward equation as describing the flow of a vector field on $M_1(\mathbb{R})$. In addition, because infinitely divisible laws play in the geometry of $M_1(\mathbb{R})$ the role^a that straight lines play in Euclidean space, he saw that one should be able to “integrate” Kolmogorov’s equation by piecing together infinitely divisible laws, just as one integrates a vector field in Euclidean space by piecing together straight lines.

Profound as the preceding idea is, Itô went a step further. Again under Lévy’s influence, he wanted to transfer his idea to a pathspace setting. Reasoning that if the transition function can be obtained by concatenating infinitely divisible laws, then the paths of the associated stochastic processes must be obtainable to concatenating paths coming from Lévy’s independent increment processes and that one should be able to encode this concatenation procedure in some sort of “differential equation” for the resulting paths. The implementation of this program required him to develop what is now called the “Itô calculus”.

It was during the period when he was working out the details of his calculus that he realized, at least in the special case when paths are continuous, there is a formula which plays role in his calculus that the chain rule plays in Newton's. This formula, which appeared for the first time in a footnote, is what we now call *Itô's formula*. Humble as its origins may have been, it has become one of the three or four most famous mathematics formulae of the twentieth century. Itô's formula is not only a boon of unquestioned and inestimable value to mathematicians but also has become an indispensable tool in the world of mathematically oriented finance.

Itô had these ideas in the early 1940s, around the time when Japan attacked Pearl Harbor and its population had to face the consequent horrors. In view of the circumstances, it is not surprising that few inside Japan, and nobody outside of Japan, knew what Itô was doing for nearly a decade. Itô did publish an outline of his program in a journal of mimeographed notes (1942) at Osaka University, but he says that only his friend G. Maruyama really read what he had written. Thus, it was not until 1950, when he sent the manuscript for a monograph to Doob who arranged that it be published by the A.M.S. as a Memoir, that Itô's work began to receive the attention which it deserved. Full appreciation of Itô's ideas by the mathematical community came only after first Doob and then H.P. McKean applied martingale theory to greatly simplify some of Itô's more technical arguments.

Despite its less than auspicious beginning, the story has a happy ending. Itô spent many years traveling the world: he has three daughters, one living in Japan, one in Denmark, and one in America. He is, in large part, responsible for the position of Japan as a major force in probability theory, and he has disciples all over the planet. His accomplishments are widely recognized: he is a member of the Japanese Academy of Sciences and the National Academy of Sciences; and he is the recipient of, among others, the Kyoto, Wolf, and Gauss Prizes. When I think of Itô's career and the rocky road that he had to travel, I recall what Jack Schwartz told a topology class I was attending about Jean Leray's invention of spectral sequences. At the time, Leray was a prisoner

in a German prison camp for French intellectuals, each of whom attempted to explain to the others something about which he was thinking. With the objective of not discussing anything that might be useful to the enemy, Leray chose to talk about algebraic topology rather than his own work on partial differential equations, and for this purpose, he introduced spectral sequences as a pedagogic tool. After relating this anecdote, Schwartz leaned back against the blackboard and spent several minutes musing about the advantages of doing research in ideal working conditions.

Kiyosi Itô died at the age of 93 on November 10, 2008. He is survived by his three daughters. A week before his death, he received the Cultural Medal from the Japanese emperor. The end of an era is fast approaching.

End Notes

^aNote that when $t \rightsquigarrow \mu_t$ is the flow of infinitely divisible law μ in the sense that $\mu_1 = \mu$ and $\mu_{s+t} = \mu_s \star \mu_t$, $\mu = (\mu_{(1/n)})^{\star n}$ for all $n \geq 1$, which is the convolution analog of $f(1) = n^{-1} f(n)$ for a linear function on $\mathbb{R}$.

DANIEL W. STROOCK

Thorp, Edward

Edward O. Thorp is a mathematician who has made seminal contributions to games of chance and investment science. He invented original strategies for the game of blackjack that revolutionized the game. Together with Sheen Kassouf, he showed how warrants could be hedged using a short position in the underlying stocks and described and implemented arbitrage portfolios of stocks and warrants. Thorp made other important contributions to the development of option pricing and to investment theory and practice. He has had a very successful record as an investment manager. This note contains a brief account of some of his major contributions.

Thorp studied physics as an undergraduate and obtained his PhD in mathematics from the University of California at Los Angeles in 1958. The title of his dissertation was *Compact Linear Operators in Normed Spaces*, and he has published several papers on functional analysis. He taught at UCLA, MIT, and New Mexico State University and was professor of mathematics and finance at the University of California at Irvine.

Thorp's interest in devising scientific systems for playing games of chance began when he was a graduate student in the late 1950s. He invented a system for playing roulette and also became interested in blackjack and devised strategies based on card counting systems. While at MIT, he collaborated with Claude Shannon, and together they developed strategies for improving the odds at roulette and blackjack. One of their inventions was a wearable computer that was the size of modern-day cell phone. In 1962, Thorp [3] published *Beat the Dealer: A Winning Strategy for the Game of Twenty One*. This book had a profound impact on the game of blackjack as gamblers tried to implement his methods, and casinos responded with various countermeasures that were sometimes less than gentle.

In June 1965, Thorp's interest in warrants was piqued by reading Sydney Fried's *RHM Warrant Survey*. He was motivated by the intellectual challenge of warrant valuation and by the prospect of making money using these instruments. He developed his initial ideas on warrant pricing and investing during the summer of 1965. Sheen Kassouf who was, like Thorp, a new faculty member at the University of California's newly established campus at Irvine, was

also interested in warrants because of his own investing. Kassouf had analyzed market data to determine the key variables that affected warrant prices. On the basis of his analysis, Kassouf developed an empirical formula for a warrant's price in terms of these variables.

In September 1965, Thorp and Kassouf discovered their mutual interest in warrant pricing and began their collaboration. In 1967, they published their book, *Beat the Market*, in which they proposed a method for hedging warrants using the underlying stock and developed a formula for the hedge ratio [5]. Their insights on warrant pricing were used^a by Black and Scholes in their landmark 1973 paper on option pricing.

Thorp and Kassouf were aware that the conventional valuation method was based on projecting the warrant's expected terminal payoff and discounting back to current time. This approach involved two troublesome parameters: the expected return on the warrant and the appropriate discount rate. Black and Scholes in their seminal paper would show that the values of both these parameters had to coincide with the riskless rate. There is strong evidence^b that Thorp independently discovered this solution in 1967 and used it in his personal investment strategies. Thorp^c makes it quite clear that the credit rightfully belongs to Black and Scholes.

Black Scholes was a watershed. It was only after seeing their proof that I was certain that this was the formula—and they justifiably get all the credit. They did two things that are required. They proved the formula(I didn't) and they published it (I didn't).

Thorp made a number of other contributions to the development of option theory and modern finance and his ideas laid the foundations for further advances. As one illustration based on my own experience, I will mention Thorp's essential contribution to a paper that David Emanuel and I published in 1980 [2]. Our paper examined the distribution of a hedged portfolio of a stock and option that was rebalanced after a short interval. The key equation on which our paper rests was first developed by Thorp in (1976) [4].

Throughout his career, Edward Thorp has applied mathematical tools to develop highly original solutions to difficult problems and he has demonstrated a unique ability to implement these solution in a practical way.

End Notes

^aBlack and Scholes state, “One of the concepts we use in developing our model was expressed by Thorp and Kassouf.”

Option Pricing Theory: Historical Perspectives

This article traces the history of the option pricing theory from the turn of the twentieth century to the present. This history documents and clarifies the origins of the key contributions (authors and papers) to the theory of option pricing and hedging. Contributions with respect to the empirical understanding of the theories are not discussed, except implicitly, because the usefulness and longevity of any model is based on its empirical validity.

It is widely agreed that the modern theory of option pricing began in 1973 with the publication of the Black–Scholes–Merton model [12, 104]. Except for the early years (pre-1973), this history is restricted to papers that use the no arbitrage and complete markets technology to price options. Equilibrium option pricing models are not discussed herein. In particular, this excludes the consideration of option pricing in incomplete markets. An outline for this article is as follows. The following section discusses the early years of option pricing (pre-1973). The remaining sections deal with 1973 to the present: the section “Equity Derivatives” discusses the Black–Scholes–Merton model; the section “Interest Rate Derivatives” concerns the Heath–Jarrow–Morton model; and the section “Credit Derivatives” corresponds to credit risk derivative pricing models.

Early Option Pricing Literature (Pre-1973)

Interestingly, many of the basic insights of option pricing originated in the early years, that is, pre-1973. It all began at the turn of the century in 1900 with Bachelier’s [4] derivation of an option pricing formula in his doctoral dissertation on the theory of speculation at France’s Sorbonne University. Although remarkably close to the Black–Scholes–Merton model, Bachelier’s formula was flawed because he used normally distributed stock prices that violated limited liability. More than half a century later, Paul Samuelson read Bachelier’s dissertation, recognized this flaw, and fixed it by using geometric Brownian motion instead in his

work on warrant pricing [117]. Samuelson derived valuation formulas for both European and American options, coining these terms in the process.

Samuelson’s derivation was almost identical to that used nearly a decade later to derive the Black–Scholes–Merton formula, except that instead of invoking the no arbitrage principle to derive the valuation formula, Samuelson postulated the condition that the discounted option’s payoffs follow a martingale (see [117], p. 19). Furthermore, it is also interesting to note that, in the appendix to this article, Samuelson and McKean determined the price of an American option by observing the correspondence between an American option’s valuation and the free boundary problem for the heat equation.

A few years later, instead of invoking the postulate that discounted option payoffs follow a martingale, Samuelson and Merton [118] derived this condition as an implication of a utility maximizing investor’s behavior. In this article, they also showed that the option’s price could be viewed as its discounted expected value, where instead of using the actual probabilities to compute the expectation, one employs utility or risk-adjusted probabilities (see expression (20) on page 26). These risk-adjusted probabilities are now known as “risk-neutral” or “equivalent martingale” probabilities. Contrary to a widely held belief, the use of “equivalent martingale probabilities” in option pricing theory predated the paper by Cox and Ross [36] by nearly 10 years (Merton (footnote 5 p. 218, [107]) points out that Samuelson knew this fact as early as 1953).

Unfortunately, these early option pricing formulas depended on the expected return on the stock, or equivalently, the stock’s risk premium. This dependency made the formulas difficult to estimate and to use. The reason for this difficulty is that the empirical finance literature has documented that the stock’s risk premium is nonstationary. It varies across time according to both changing tastes and changing economic fundamentals. This nonstationarity makes both the modeling of risk premium and their estimation problematic. Indeed, at present, there is still no generally accepted model for an asset’s risk premium that is consistent with historical data (see [32], Part IV for a review).

Perhaps the most important criticism of this early approach to option pricing is that it did not invoke the riskless hedging argument in conjunction with the no-arbitrage principle to price an option. (The first use of

riskless hedging with no arbitrage to prove a pricing relationship between financial securities can be found in [110].) And, as such, these valuation formulas provided no insights into how to hedge an option using the underlying stock and riskless borrowing. It can be argued that the idea of hedging an option is the single most important insight of modern option pricing theory. The use of the no arbitrage hedging argument to price an option can be traced to the seminal papers by Black and Scholes [12] and Merton [104], although the no arbitrage hedging argument itself has been attributed to Merton (see [79] in this regard).

Equity Derivatives

Fischer Black, Myron Scholes, and Robert Merton pioneered the modern theory of option pricing with the publication of the Black–Scholes–Merton option pricing model [12, 104] in 1973. The original Black–Scholes–Merton model is based on five assumptions: (i) competitive markets, (ii) frictionless markets, (iii) geometric Brownian motion, (iv) deterministic interest rates, and (v) no credit risk. For the purposes of this section, the defining characteristics of this model are the assumptions of deterministic interest rates and no credit risk.

The original derivation followed an economic hedging argument. The hedging argument involves holding simultaneous and offsetting positions in a stock and option that generates an instantaneous riskless position. This, in turn, implies a partial differential equation (pde.) for the option's value that is subject to a set of boundary conditions. The solution under geometric Brownian motion is the Black–Scholes formula.

It was not until six years later that the martingale pricing technology was introduced by Harrison and Kreps [65] and Harrison and Pliska [66, 67], providing an alternative derivation of the Black–Scholes–Merton model. These papers, and later refinements by Delbaen and Schachermayer [40, 41, 42], introduced the first and second fundamental theorems of asset pricing, thereby providing the rigorous foundations to option pricing theory.

Roughly speaking, the first fundamental theorem of asset pricing states that no arbitrage is equivalent to the existence of an equivalent martingale probability measure, that is, a probability measure that makes

the discounted stock price process a martingale. The second fundamental theorem of asset pricing states that the market is complete if and only if the equivalent martingale measure is unique. A complete market is one in which any derivative security's payoffs can be generated by a dynamic trading strategy in the stock and riskless asset. These two theorems enabled the full fledged use of stochastic calculus for option pricing theory. A review and summary of these results can be found in [43].

At the beginning, this alternative and more formal approach to option pricing theory was viewed as only of tangential interest. Indeed, all existing option pricing theorems could be derived without this technology and only using the more intuitive economic hedging argument. It was not until the Heath–Jarrow–Morton (HJM) model [70] was developed—circulating as a working paper in 1987—that this impression changed. The HJM model was the first significant application that could not be derived without the use of the martingale pricing technology. More discussion relating to the HJM model is contained in the section “Interest Rate Derivatives”.

Extensions

The original Black–Scholes–Merton model is based on the following five assumptions: (i) competitive markets, (ii) frictionless markets, (iii) geometric Brownian motion, (iv) deterministic interest rates, and (v) no credit risk. The first two assumptions—competitive and frictionless markets—are the mainstay of finance. Competitive markets means that all traders act as price takers, believing their trades have no impact on the market price. Frictionless markets imply that there are no transaction costs nor trade restrictions, for example, no short sale constraints. Geometric Brownian motion implies that the stock price is lognormally distributed with a constant volatility. Deterministic interest rates are self-explanatory. No credit risk means that the investors (all counterparties) who trade financial securities will not default on their obligations.

Extensions of the Black–Scholes–Merton model that relaxed assumptions (i)–(iii) quickly flourished. Significant papers relaxing the geometric Brownian motion assumption include those by Merton [106] and Cox and Ross [36], who studied jump and jump-diffusion processes. Merton's paper [106] also

included the insight that if unhedgeable jump risk is diversifiable, then it carries no risk premium. Under this assumption, one can value jump risk using the statistical probability measure, enabling the simple pricing of options in an incomplete market. This insight was subsequently invoked in the context of stochastic volatility option pricing and in the context of pricing credit risk derivatives.

Merton [104], Cox [34] and Cox and Ross [36] were among the first to study stochastic volatility option pricing in a complete market. Option pricing with stochastic volatility in incomplete markets was subsequently studied by Hull and White [73] and Heston [71]. More recent developments in this line of research use a HJM [70] type model with a term structure of forward volatilities (see [51, 52]). Stochastic volatility models are of considerable current interest in the pricing of volatility swaps, variance swaps, and options on variance swaps.

A new class of Levy processes was introduced by Madan and Milne [102] into option pricing and generalized by Carr *et al.* [20]. Levy processes have the nice property that their characteristic function is known, and it can be shown that an option's price can be represented in terms of the stock price's characteristic function. This leads to some alternative numerical procedures for computing option values using fast Fourier transforms (see [23]). For a survey of the use of Levy processes in option pricing, see [33].

The relaxation of the frictionless market assumption has received less attention in the literature. The inclusion of transaction costs into option pricing was originally studied by Leland [99], while Heath and Jarrow [69] studied the imposition of margin requirements. A more recent investigation into the impact of transaction costs on option pricing, using the martingale pricing technology, can be found in [26].

The relaxation of the competitive market assumption was first studied by Jarrow [77, 78] *via* the consideration of a large trader whose trades change the price. Jarrow's approach maintains the no arbitrage assumption, or in this context, a no market manipulation assumption (see also [5]).

In between a market with competitive traders and a market with a large trader is a market where traders have only a temporary impact on the market price. That is, purchase/sales change the price paid/received depending upon a given supply curve. Traders act as price takers with respect to the supply curve. Such a

price impact is called *liquidity risk*. Liquidity risk, of this type, can be considered as an endogenous transaction cost. This extension is studied in [26]. Liquidity risk is currently a hot research topic in option pricing theory.

The Black–Scholes–Merton model has been applied to foreign currency options (see [58]) and to all types of exotic options on both equities and foreign currencies. A complete reference for exotic options is [44].

Computations

The original derivation of the Black–Scholes–Merton model yields an option's value satisfying a pde, subject to a set of boundary conditions. For a European call or put option, under geometric Brownian motion, the pde has an analytic solution. For American options under geometric Brownian motion, analytic solutions are not available for puts independent of dividend payments on the underlying stock, and for American calls with dividends. For different stock price processes, analytic solutions are often not available as well, even for European options. In these cases, numerical solutions are needed. The first numerical approaches employed in this regard were finite difference methods (see [15, 16]).

Closely related, but containing more economic intuition, option prices can also be computed numerically by using a binomial approximation. The first users in this regard were Sharpe [122] chapter 16, and Rendleman and Barter [113]. Cox *et al.* [37] published the definitive paper documenting the binomial model and its convergence to the continuous time limit (see also [68]). A related paper on convergence of discrete time models to continuous time models is that by Duffie and Protter [48].

The binomial pricing model, as it is now known, is also an extremely useful pedagogical device for explaining option pricing theory. This is true because the binomial model uses only discrete time mathematics. As such, it is usually the first model presented in standard option pricing textbooks. It is interesting to note that both the first two textbooks on option pricing utilized the binomial model in this fashion (see [38] and [84]).

Another technique for computing option values is to use a series expansions (see [50, 83 and 123]). Series expansions are also useful for hedging exotic options that employ only static hedge positions with

plain vanilla options (see [38] chapter 7.2, [24, 63, and 116]).

As computing a European option's price is equivalent to computing an expectation, an alternative approach to either finite difference methods or the binomial model is Monte Carlo simulation. The paper that introduced this technique to option pricing is by Boyle [13]. This technique has become very popular because of its simplicity and its ability to handle high-dimensional problems (greater than three dimensions). This technique has also recently been extended to pricing American options. Important contributions in this regard are by Longstaff and Schwartz [101] and Broadie and Glasserman [18]. For a complete reference on Monte Carlo techniques, see [61].

Following the publication of Merton's original paper [104], which contained an analytic solution for a perpetual American put option, much energy has been expended in the search for analytic solutions for both American puts and calls with finite maturities. For the American call, with a finite number of known dividends, a solution was provided by Roll [115]. For American puts, breaking the maturity of the option into a finite number of discrete intervals, the compound option pricing technique is applicable, (see [60] and [93]). More recently, the decomposition of American options into a European option and an early exercise premium was discovered by Carr *et al.* [22], Kim [96], and Jacka [75].

These computational procedures are more generally applicable to all derivative pricing models, including those discussed in the next two sections.

Interest Rate Derivatives

Interest rate derivative pricing models provided the next major advance in option pricing theory. Recall that a defining characteristic of the Black–Scholes–Merton model is that it assumes deterministic interest rates. This assumption limits its usefulness in two ways. First, it cannot be used for long-dated contracts. Indeed, for long-dated contracts (greater than a year or two), interest rates cannot be approximated as being deterministic. Second, for short-dated contracts, if the underlying asset's price process is highly correlated with interest rate movements, then interest rate risk will affect hedging, and therefore valuation. The extreme cases, of course, are interest rate derivatives where the underlyings are the interest rates themselves.

During the late 1970s and 1980s, interest rates were large and volatile, relative to historical norms. New interest rate risk management tools were needed because the Black–Scholes–Merton model was not useful in this regard. In response, a class of interest rate pricing models were developed by Vasicek [124], Brennan and Schwartz [17], and Cox *et al.* (CIR) [35]. This class, called the *spot rate models*, had two limitations. First, they depended on the market price(s) of interest rate risk, or equivalently, the expected return on default free bonds. This dependence, just as with the option pricing models pre-Black–Scholes–Merton, made their implementation problematic. Second, these models could not easily match the initial yield curve. This calibration is essential for the accurate pricing and hedging of interest rate derivatives because any discrepancies in yield curve matching may indicate “false” arbitrage opportunities in the priced derivatives.

To address these problems, Ho and Lee [72] applied the binomial model to interest rate derivatives with a twist. Instead of imposing an evolution on the spot rate, they had the zero coupon bond price curve that evolved in a binomial tree. Motivated by this paper, Heath–Jarrow–Morton [70] generalized this idea in the context of a continuous time and multifactor model to price interest rate derivatives. The key step in the derivation of the HJM model was determined as the necessary and sufficient conditions for an arbitrage free evolution of the term structure of interest rates.

The defining characteristic of the HJM model is that there is a continuum of underlying assets, a term structure, whose correlated evolution needs to be considered when pricing and hedging options. For interest rate derivatives, this term structure is the term structure of interest rates. To be specific, it is the term structure of default free interest rates. But there are other term structures of relevance, including foreign interest rates, commodity futures prices, convenience yields on commodities, and equity forward volatilities. These alternative applications are discussed later in this section.

To simplify the mathematics, HJM focused on forward rates instead of zero-coupon bond prices. The martingale pricing technology was the tool used to obtain the desired conditions —the “HJM drift conditions”. Given the HJM drift conditions and the fact that the interest rate derivative market is

complete in the HJM model, standard techniques are then applied to price interest rate derivatives.

The HJM model is very general: all previous spot rate models are special cases. In fact, the labels Vasicek, extended Vasicek (or sometimes Hull and White [74]), and CIR are now exclusively used to identify subclasses of the HJM model. Subclasses are uniquely identified by a particular volatility structure for the evolution of forward rate curve. For example, the Ho and Lee model is now identified as a single factor HJM model, where the forward rate volatility is a constant across maturities. This can be shown to be the term structure evolution to which the Ho and Lee binomial model converges.

Adoption of the HJM model was slow at first, hampered mostly by computational concerns, but as these computational concerns dissipated, the modern era for pricing interest rate derivatives was born. As mentioned previously, the HJM model was very general. In its most unrestricted form, the evolution of the term structure of interest rates could be path dependent (non-Markov) and it could generate negative interest rates with positive probability. Research into the HJM model proceeded in two directions: (i) investigations into the abstract mathematical structure of HJM models and (ii) studying subclasses that had nice analytic and computational properties for applications.

With respect to the understanding of the mathematical structure of HJM models, three questions arose. First, what structures would guarantee interest rates that remained positive? Second, given an initial forward rate curve and its evolution, what is the class of forward rate curves that can be generated by all possible evolutions? Third, under what conditions is an HJM model a finite dimensional Markov process? The first question was answered by Flesaker and Hughston [55], Rogers [114], and Jin and Glasserman [91]. The second was solved by Bjork and Christensen [7] and Filipovic [56]. The third was studied by Cheyette [30], Caverhill [25], Jeffrey [92], Duffie and Kan [45], and Bjork and Svensson [9], among others.

The original HJM model had the term structure of interest rates generated by a finite number of Brownian motions. Extensions include (i) jump processes (see [8, 53 and 82]); (ii) stochastic volatilities (see [1, 31]); and (iii) random fields (see [64, 95]).

Subclasses

Subsequent research developed special cases of the HJM model that have nice analytic and computational properties for implementation. Perhaps the most useful class, for its analytic properties, is the affine model of Duffie and Kan [45] and Dai and Singleton [39]. The class of models is called *affine* because the spot rate can be written as an affine function of a given set of state variables. The affine class includes both the Vasicek and CIR models as mentioned earlier. This class of term structure evolutions have known characteristic functions for the spot rate, which enables numerical computations for various interest rate derivatives (see [47]). Extensions of the affine class include those by Filipovic [57], Chen *et al.* [28], and Cheng and Scaillet [29].

The original HJM paper showed that instantaneous forward rates being lognormally distributed is inconsistent with no arbitrage. Hence, geometric Brownian motion was excluded as an acceptable forward rate process. This was unfortunate because it implies that caplets, options on forward rates, will not satisfy Black's formula [10]. And historically, because of the industry's familiarity with the Black–Scholes formula (a close relative of Black's formula), Black's formula was used extensively to value caplets. This inconsistency between theory and practice lead to a search for a theoretical justification for using Black's formula with caplets.

This problem was resolved by Sandmann *et al.* [119], Miltersen *et al.* [109], and Brace *et al.* [14]. The solution was to use a simple interest rate, compounded discretely, for the London Interbank Offer Rate (LIBOR). Of course, simple rates better match practice. And it was shown that the evolution of a simple LIBOR could evolve as a geometric Brownian motion in an arbitrage free setting. Subsequently, the lognormal evolution has been extended to jump diffusions (see [62]), Levy processes (see [54]), and stochastic volatilities (see [1]).

Key to the use of the “LIBOR model”, as it has become known, is the forward price martingale measure. The forward price martingale measure is an equivalent probability measure that makes asset payoffs at some future date T martingales when discounted by the T maturity zero coupon bond price. The forward price martingale measure

was first discovered by Jarrow [76] and later independently discovered by Geman [59] (see [112] for a discussion of the LIBOR model and its history).

Applications

The HJM model has been extended to multiple term structures and applied to foreign currency derivatives [2], to equities and commodities [3], and to Treasury inflation protected bonds [89]. The HJM model has also been applied to term structures of futures prices (see [21], and [108]), term structures of convenience yields [111], term structures of credit risky bonds (discussed in the next section), and term structures of equity forward volatilities ([51, 52], and [121]). In fact, it can be shown that almost all option pricing applications can be viewed as special cases of a multiple term structure HJM model (see [88]). A summary of many of these applications can be found in [19].

Credit Derivatives

The previously discussed models excluded the consideration of default when trading financial securities. The first model for studying credit risk, called the *structural approach*, was introduced by Merton [105]. Credit risk, although always an important consideration in fixed income markets, dramatically expanded its market wide recognition with the introduction of trading in credit default swaps after the mid-1990s. The reason for this delayed importance was that it took until then for the interest rate derivative markets to mature sufficiently for sophisticated financial institutions to successfully manage/hedge equity, foreign currency and interest rate risk. This risk-controlling ability enabled firms to seek out arbitrage opportunities, and in the process, lever up on the remaining financial risks, which are credit/counterparty, liquidity, and operational risk. This greater risk exposure by financial institutions to both credit and liquidity risk (as evidenced by the events surrounding the failure of Long Term Capital Management) spurred the more rapid development of credit risk modeling.

As the first serious contribution to credit risk modeling, Merton's original model was purposely simple. Merton considered credit risk in the context

of a firm issuing only a single zero coupon bond. As such, risky debt could be decomposed into riskless debt plus a short put option on the assets of the firm. Shortly thereafter, extensions to address this simple liability structure were quickly discovered by Black and Cox [11] Jones *et al.* [94] and Leland [100] among others.

The structural approach to credit risk modeling has two well-known empirical shortcomings: (i) that default occurs smoothly, implying that bond prices do not jump at default and (ii) that the firm's assets are neither traded nor observable. The first shortcoming means that for short maturity bonds, credit spreads as implied by the structural model are smaller than those observed in practice. Extensions of the structural approach that address the absence of a jump at default include that by Zhou [125]. These extensions, however, did not overcome the second shortcoming.

Almost 20 years after Merton's original paper, Jarrow and Turnbull [85, 86] developed an alternative credit risk model that overcame the second shortcoming. As a corollary, this approach also overcame the first shortcoming. This alternative approach has become known as the *reduced form model*. Early important contributions to the reduced form model were by Lando [97], Madan and Unal [103], Jarrow *et al.* [80], and Duffie and Singleton [49].

As the credit derivative markets expanded, so did extensions to the reduced form model. To consider credit rating migration, Jarrow *et al.* [80] introduced a Markov chain model, where the states correspond to credit ratings. Next, there was the issue of default correlation for pricing credit derivatives on baskets (e.g., credit default obligations (CDOs)). This correlation was first handled with Cox processes (Lando [97]).

The use of Cox processes induces default correlations across firms through common state variables that drive the default intensities. But when conditioning on the state variables, defaults are assumed to be independent across firms. If this structure is true, then after conditioning, defaults are diversifiable in a large portfolio and require no additional risk premium. The implication is that the empirical and risk neutral default intensities are equal. This equality, of course, would considerably simplify direct estimation of the risk neutral default intensity [81].

This is not the only mechanism through which default correlations can be generated. Default contagion is also possible through competitive industry considerations. This type of default contagion is a type of “counterparty” risk, and it was first studied in the context of a reduced form model by Jarrow and Yu [90]. “Counterparty risk” in a reduced form model, an issue in and of itself, was previously studied by Jarrow and Turnbull [86, 87].

Finally, default correlation could be induced *via* information flows as well. Indeed, a default by one firm may cause other firm’s default intensities to increase as the market learns about the reasons for the realized default (see [120]). Finding a suitable correlation structure for implementation and estimation is still a topic of considerable interest.

An important contribution to the credit risk model literature was the integration of structural and reduced form models. These two credit risk models can be understood through the information sets used in their construction. Structural models use the management’s information set, while reduced form models use the market’s information set. Indeed, the manager has access to the firm’s asset values, while the market does not. The first paper making this connection was by Duffie and Lando [46] who viewed the market as having the management’s information set plus noise, due to the accounting process. An alternative view is that the market has a coarser partitioning of management’s information, that is, less of it. Both views are reasonable, but the mathematics is quite different. The second approach was first explored by Cetin *et al.* [27].

Credit risk modeling continues to be a hot area of research. Books on the current state of the art with respect to credit risk derivative pricing models are by Lando [98] and Bielecki and Rutkowski [6].

ROBERT A. JARROW

Modern Portfolio Theory

Modern portfolio theory (MPT) is generally defined as the body of financial economics beginning with Markowitz' famous 1952 paper, "Portfolio Selection", and extending through the next several decades of research into what has variously been called *Financial Decision Making under Uncertainty*, *The Theory of Investments*, *The Theory of Financial Economics*, *Theory of Asset Selection and Capital–Market Equilibrium*, and *The Revolutionary Idea of Finance* [45, 53, 58, 82, 88, 98]. Usually this definition includes the Capital Asset Pricing Model (CAPM) and its various extensions. Markowitz once remarked to Marschak that the first "CAPM" should be attributed to Marschak because of his pioneering work in the field [56]; Marschak politely declined the honor.

The original CAPM, as we understand it today, was first developed by Treynor [91, 92], and subsequently independently derived in the works of Sharpe [84], Lintner [47], and Mossin [65]. With the exception of some commercially successful multifactor models that implement the approaches pioneered in [71, 72, 74, 75], most practitioners have little use for market models other than the CAPM, although (or, perhaps rather, *because of* the simplicity it derives from the fact that) its conclusions are based on extremely restrictive and unrealistic assumptions. Academics have spent much time and effort attempting to substantiate or refute the validity of the CAPM as a positive economic model. The best examples of such attempts are [13, 28]. Roll [70] effectively ended this debate, however, by demonstrating that, since the "market portfolio" is not measurable, the CAPM can never be empirically proven or disproven.

History of Modern Portfolio Theory

The history of MPT extends back farther than the history of CAPM, to Tobin [90], Markowitz [53], and Roy [78], all of whom consider the "price of risk". For more detailed treatments of MPT and pre-MPT financial economic thought, refer to [22, 69, 82]. The prehistory of MPT can be traced further yet, to Hicks [34] who includes the "price of risk" in his discussion of commodity futures and to Williams [95] who considers stock prices to

be determined by the present value of discounted future dividends. MPT prehistory can be traced even beyond to Bachelier [3], who was the first to describe arithmetic Brownian motion with the objective of determining the value of financial derivatives, all the way to Bernoulli [7], who originated the concept of risk aversion while working to solve the St. Petersburg Paradox. Bernoulli, in his derivation of logarithmic utility, suggested that people maximize "moral expectation"—what we call today *expected utility*; further, Bernoulli, like Markowitz [53] and Roy [78], advised risk-averse investors to diversify: "... it is advisable to divide goods which are exposed to some small danger into several portions rather than to risk them all together."

Notwithstanding this ancient history, MPT is inextricably connected to CAPM, which for the first time placed the investor's problem in the context of an economic equilibrium. This modern approach finds its origin in the work of Mossin [65], Lintner [47, 48], and Sharpe [84], and even earlier in Treynor [91, 92]. Accounts of these origins can be found in [8, 29, 85]. Treynor [92] built on the single-period discrete-time foundation of Markowitz [53, 54] and Tobin [90]. Similar CAPM models of this type were later published in [47, 48, 84]. Mossin [65] clarified Sharpe [84] by providing a more precise specification of the equilibrium conditions. Fama [26] reconciled the Sharpe and Lintner models; Lintner [49] incorporated heterogeneous beliefs; and Mayers [57] allowed for concentrated portfolios through trading restrictions on risky assets, transactions costs, and information asymmetries. Black [10] utilized the two-fund separation theorem to construct the zero-beta CAPM, by using a portfolio that is orthogonal to the market portfolio in place of a risk-free asset. Rubinstein [79] extended the model to higher moments and also (independently of Black) derived the CAPM without a riskless asset.

Discrete-time multiperiod models were the next step; these models generally extend the discrete-time single-period model into an intertemporal setting in which investors maximize the expected utility of lifetime consumption and bequests. Building upon the multiperiod lifetime consumption literature of Phelps [68], Mirrlees [63], Yaari [97], Levhari and Srinivasan [44], and Hahn [30], models of this type include those of Merton [59, 60], Samuelson [83], Hakansson [31, 32], Fama [27], Beja [4], Rubinstein [80, 81], Long [50, 51], Kraus and Litzenberger

[41], and culminate in the consumption CAPMs (CCAPMs) of Lucas [52] and Breeden [15].

The multiperiod approach was taken to its continuous-time limit in the intertemporal CAPM (“ICAPM”) of Merton [61]. In addition to the standard assumptions—limited liability of assets, no market frictions, individual trading does not affect prices, the market is in equilibrium, a perfect borrowing and lending market exists, and no nonnegativity constraints (relaxing the no short-sale rule employed by Tobin and Sharpe but not by Treynor and Lintner)—this model assumes that trading takes place continually through time, as opposed to at discrete points in time. Rather than assuming normally distributed security returns, the ICAPM assumes a log-normal distribution of prices and a geometric Brownian motion of security returns. Also, the constant rate of interest provided by the risk-free asset in the CAPM is replaced by a dynamically changing rate, which is certain in the next instant but uncertain in the future. Williams [96] extended this model by relaxing the homogeneous expectations assumption, and Duffie and Huang [23] confirmed that such a relaxation is consistent with the ICAPM. The continuous-time model was shown to be consistent with a single-beta CCAPM by Breeden [15]. Hellwig [33] and Duffie and Huang [24] construct continuous-time models that allow for informational asymmetries. The continuous-time model was further extended to include macroeconomic factors in [20]. Kyle [42] constructs an ICAPM to model insider trading.

These, and other CAPMs, including the international models of Black [12], Solnik [86], and Stulz [89], as well as the CAPMs of Ross [73, 76] and Stapleton and Subrahmanyam [87], are reviewed in [16, 17, 19, 62, 77]. Bergstrom [5] provides a survey of continuous-time models.

Extensions of the CAPM have also been developed for use, in particular, in industrial applications; for example, Cummins [21] reviews the models of Cooper [18], Biger and Kahane [9], Fairley [25], Kahane [39], Hill [35], Ang and Lai [2], and Turner [94], which are specific to the insurance industry. More recent work continues to extend the theory. Nielsen [66, 67], Allingham [1], and Berk [6] examine conditions for equilibrium in the CAPM. Current research, such as the collateral adjusted CCAPM of

Hindy and Huang [36] and the parsimonious conditional discrete-time CAPM and simplified infinite-date model of LeRoy [43], continues to build upon the model originated in [91]. Each is perhaps more realistic, if less elegant, than the original. And yet it is the single period, discrete-time CAPM that has become popular and endured, as all great models do, precisely *because* it is simple and unrealistic. It is realistic enough, apparently, to be coincident with the utility functions of great many agents.

A Perspective on CAPM

One of the puzzles that confronts the historian of CAPM is the changing attitude over time and across different scholarly communities toward the seminal work of Treynor [91, 92]. Contemporaries consistently cited the latter paper [11, 13, 37, 38], including also [84, 85]. However, in other papers, such as [16, 45, 55], these citations were not made. Histories and bibliographies continue to take note of Treynor’s contribution [8, 14, 58, 82], but not textbooks or the scholarly literature that builds on CAPM. Why not?

One reason is certainly that Treynor’s manuscript [92] was not actually published in a book until much later [40], although the paper did circulate widely in mimeograph form. Another is that Treynor never held a permanent academic post, and so did not have a community of students and academic colleagues to draw attention to his work. A third is that, although Treynor continued to write on financial topics, writings collected in [93], these writings were consistently addressed to practitioners, not to an academic audience.

Even more than these, perhaps the most important reason (paradoxically) is the enormous attention that was paid in subsequent years to refinement of MPT. Unlike Markowitz and Sharpe, Treynor came to CAPM from a concern about the firm’s capital budgeting problem, not the investor’s portfolio allocation problem. (This concern is clear in the 1961 draft, which builds explicitly on [64].) This was the same concern, of course, that motivated Lintner, and it is significant therefore that the CAPMs of Lintner and Sharpe were originally seen as different theories, rather than different formulations of the same theory.

Because the portfolio choice problem became such a dominant strand of academic research, it

was perhaps inevitable that retrospective accounts of CAPM would emphasize the line of development that passes from the individual investor's problem to the general equilibrium problem, which is to say the line that passes through Tobin and Markowitz to Sharpe. Lintner and Mossin come in for some attention, as academics who contributed not only their own version of CAPM but also produced a series of additional contributions to the academic literature. However, Treynor was not only interested in a different problem but also was, and remained, a practitioner.

Conclusion

In 1990, the world beyond financial economists was made aware of the importance of MPT, when Markowitz and Sharpe, along with Miller, were awarded the Nobel Prize in Economics for their roles in the development of MPT. In the presentation speech, Assar Lindbeck of the Royal Swedish Academy of Sciences said "Before the 1950s, there was hardly any theory whatsoever of financial markets. A first pioneering contribution in the field was made by Harry Markowitz, who developed a theory . . . [which] shows how the multidimensional problem of investing under conditions of uncertainty in a large number of assets . . . may be reduced to the issue of a trade-off between only two dimensions, namely the expected return and the variance of the return of the portfolio The next step in the analysis is to explain how these asset prices are determined. This was achieved by development of the so-called Capital Asset Pricing Model, or CAPM. It is for this contribution that William Sharpe has been awarded. The CAPM shows that the optimum risk portfolio of a financial investor depends only on the portfolio manager's prediction about the prospects of different assets, not on his own risk preferences The Capital Asset Pricing Model has become the backbone of modern price theory of financial markets" [46].

Long-Term Capital Management

Background

Long-Term Capital Management (LTCM) launched its flagship fund on February 24, 1994, with \$1.125 billion in capital, making it the largest start-up hedge fund to date. Over \$100 million came from the partners themselves, especially those who came from the proprietary trading operation that John Meriwether had headed at Salomon Brothers. At Salomon, the profit generated by this group had regularly exceeded the profit generated by the entire firm, and the idea of LTCM was to continue this record on their own. To help them, they also recruited a dream team of academic talent, most notably Myron Scholes and Robert Merton (*see Merton, Robert C.*), who would win the 1997 Nobel Prize in Economics for their pioneering work in financial economics. But they were not alone; half of the founding partners taught finance at major business schools.

The first few years of the fund continued the success of the Salomon years (Table 1).

The fund was closed to new capital in 1995 and quickly grew to \$7.5 billion of capital by the end of 1997. At this time the partners decided, given the lack of additional opportunities, to pay a dividend of \$2.7 billion, which left the capital at the beginning of 1998 at \$4.8 billion.

Investment Style

The fund invested in relative-value convergence trades. They would buy cheap assets and hedge as many of the systematic risk factors as possible by selling rich assets. The resulting “spread” trade had significantly less risk than the outright trade,

so LTCM would lever the spread trade to raise the overall risk level, as well as the expected return on invested capital.

An example of such a trade is an on-the-run *versus* off-the-run trade. In August 1998, 30-year treasuries (the on-the-run bond) had a yield to maturity of 5.50%. The 29-year bond (the off-the-run issue) was 12 basis points (bp) cheaper, with a yield to maturity of 5.62%. The outright risk of 30-year treasury bonds was a standard deviation of around 85 bp per year. The spread trade only had a risk level of around 3.5 bp per year, so the spread trade could be levered 25 to 30 to 1, bringing it in line with the market risk of 30-year treasuries.

LTCM would never do a trade that mathematically looked attractive according to its models unless they qualitatively understood why the trade worked and what were the forces that would bring the “spreads” to convergence. In the case of the on-the-run versus off-the-run trade, the main force leading to a difference in yields between the two bonds is liquidity. The 30-year bond is priced higher by 12 bp (approximately 1.2 points on a par bond) because some investors are willing to pay more to own a more liquid bond. But in six months’ time, when the treasury issues a new 30-year bond, that new bond will be the most liquid one and the old 30-year bond will lose its liquidity premium. This means that in six months’ time, it will trade at a yield similar to that of the old 29-year bond, thus bringing about a convergence of the spread.

LTCM was involved in many such relative-value trades, in many different and seemingly unrelated markets and instruments. These included trades in Government bond spreads, swap spreads, yield curve arbitrage, mortgage arbitrage, volatility spreads, risk arbitrage, and equity relative value trades. In each case, the bet was that some spread would converge over time.

Risk Management

LTCM knew that a major risk to pursuing relative-value convergence trades was the ability to hold the trades until they converged. To ensure this, LTCM insisted that investors lock in equity capital for 3 years, so there would be no premature liquidation from investor cashout. This equity lock-in also gave counterparties comfort that LTCM had long-lasting

Table 1 LTCM returns

Year	Net return (%)	Gross return (%)	Dollar profits (\$)	Ending capital (\$)
1994	20	28	0.4	1.6
1995	43	59	1.3	3.6
1996	41	57	2.1	5.2
1997	17	25	1.4	7.5

credit worthiness, and that enabled LTCM to acquire preferential financing.

As a further protection, LTCM also made extensive use of term financing. If the on-the-run/off-the-run trade might take six months to converge, LTCM would finance the securities for six months, instead of rolling the financing overnight. LTCM also had a two-way mark-to-market provisions in all of its over-the-counter contracts. Thus for its relative value trades that consisted of both securities and contractual agreements it had fully symmetric marks, so that the only time LTCM had to put additional equity capital into a trade was if the spreads widened out. The fund also had term debt and backstop credit lines in place as alternative funding.

LTCM also stress tested its portfolio relative to potential economic shocks to the system, and hedged against the consequences. As an example, in 1995, LTCM had a large swapped position in Italian government bonds. The firm got very worried that if the Republic of Italy defaulted, it would have a sizable loss. So it purchased insurance against this potential default by doing a credit default swap on the Italian government bonds.

But the primary source of risk management relied on the benefit that the portfolio obtained due to

diversification. If the relative value strategies had very low correlations with each other, then the risk of the overall portfolio would be low. LTCM assumed that in the long run these correlations were low because of the loose economic ties between the trades, although in the short run these correlations could be significantly higher. LTCM also assumed that the downside risk on some of the trades was diminished, as spreads got very wide, on the assumption that other leveraged funds would rush in to take advantage. In retrospect, these assumptions were all falsified by experience.

Before the crisis, LTCM had a historical risk level of a \$45 million daily standard deviation of return on the fund. See Figure 1 for historical daily returns.

After the fund reached global scale in 1995, the risk level was remarkably stable. In fact, the partners had actually predicted a higher risk level for the fund as they assumed that the correlations among the relative value trades would be higher than historical levels. But in 1998, all this changed.

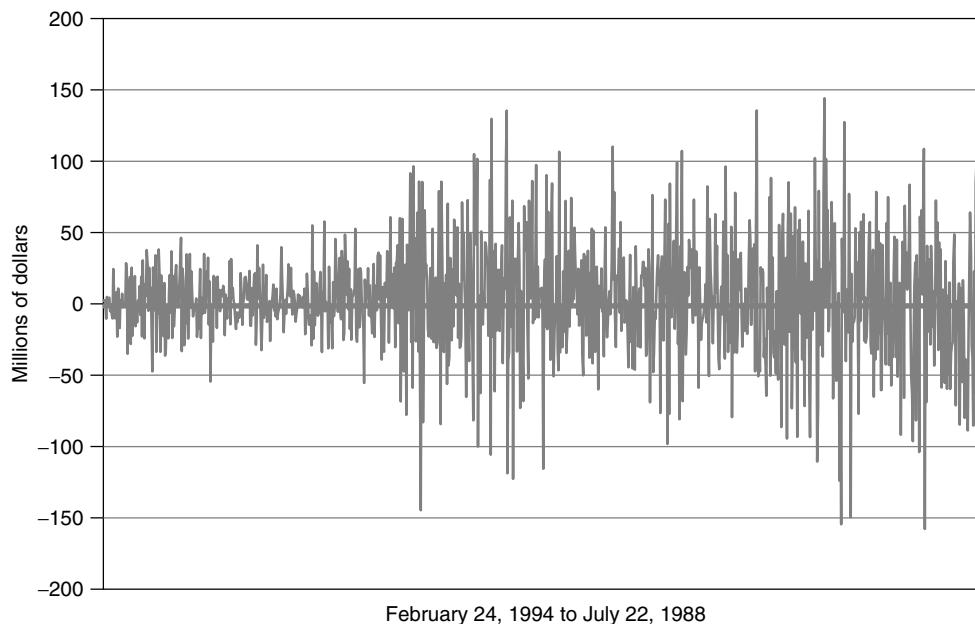

Figure 1 Historical daily returns

The 1998 Crisis

In 1998, LTCM was up slightly in the first four months of the year. Then, in May, the portfolio lost 6% and in June, it lost 10%. In early July, the portfolio rebounded by about 7% and the partners reduced the underlying risk of the portfolio accordingly by about 10%.

The crisis was triggered by the Russian default on its domestic bonds on August 17, 1998. While LTCM did not have many Russian positions so that its direct losses were small, the default did initiate the process that was to follow as unrelated markets all over the world reacted. On Friday August 21, LTCM had a one-day loss of \$550 million. (A risk arb deal that was set to close on that day, that of Ciena and Tellabs, broke, causing a \$160 million loss. Swap spreads that normally move about 1 bp a day were out 21 bp intraday.) The Russian debt crisis had triggered a flight out of all relative-value positions. In the illiquid days at the end of August, these liquidations caused a downward spiral as new losses led to more liquidations and more losses. The result was that by the end of August LTCM was down by 53% for the year, with the capital now at \$2.3 billion.

While the Russian default triggered the economic crisis in August, it was an LTCM crisis in September. Would the fund fail? Many other institutions with similar positions liquidated them in advance of the potential failure. Some market participants bet against the firm and counterparties marked contractual agreements at extremely wide levels to obtain additional cushions against bankruptcy. The partners hired Goldman Sachs to help them raise additional capital and to sell off assets; for this, they received 50% of the management company.

The leverage of the firm went to an enormous levels involuntarily (Figure 2), not because of increase in assets but because of equity falling. In the event, attempts to raise additional funds failed and on Monday, September 21, the fund lost another \$550 million, putting its capital for the first time below \$1 billion. On Wednesday, at the behest of the Federal Reserve, the 15 major counterparties met at the New York Fed to discuss the situation.

During the meeting, at 11:00 AM the partners received a telephone call from Warren Buffett, who was on a satellite phone while vacationing with Bill Gates in Alaska. He said that LTCM was about to receive a bid on its entire portfolio from him and that he hoped they would seriously consider it. At 11:30 AM LTCM received the fax message given in Figure 3.

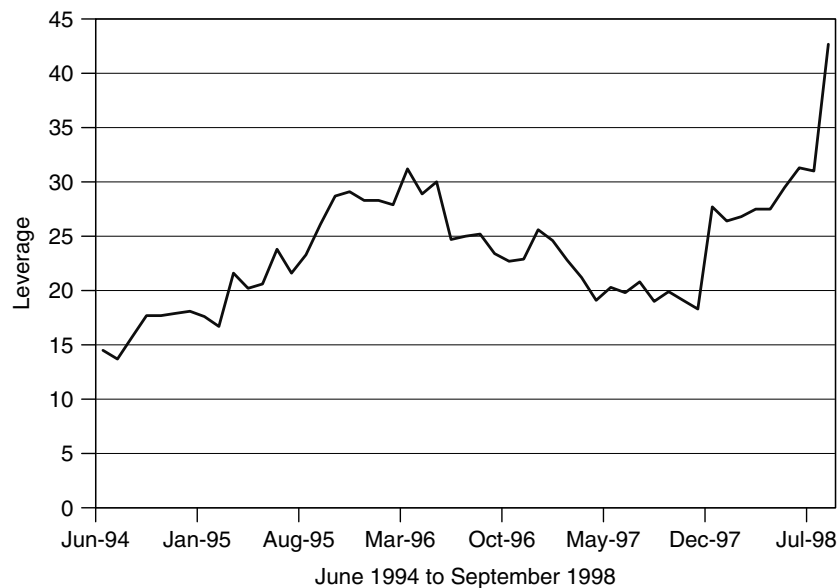

Figure 2 Leverage

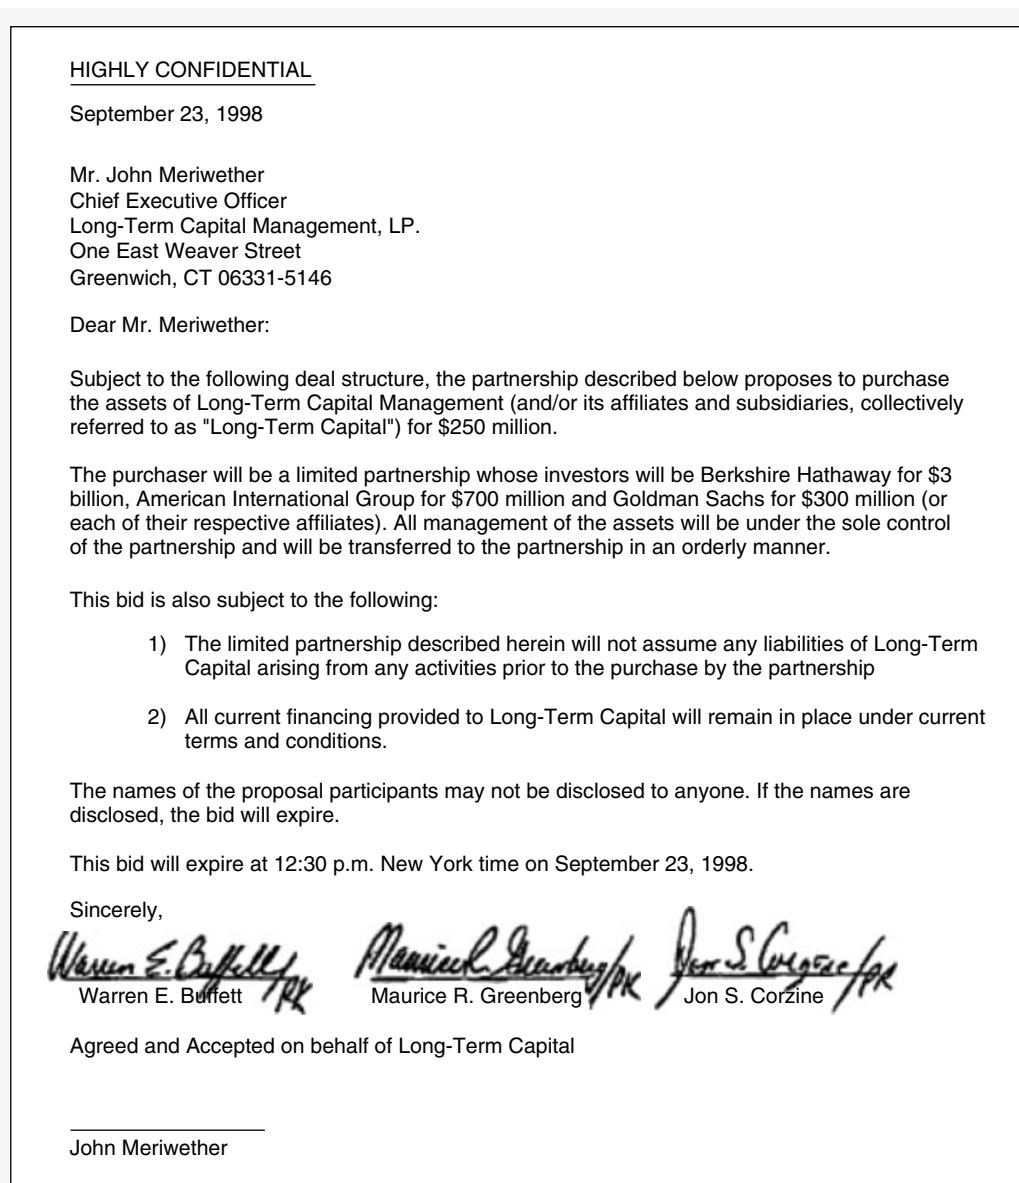

Figure 3 Copy of the \$250 million offer for Long-Term Capital Management

The partners were unable to accept the proposal as it was crafted. The fund had approximately 15 000 distinct positions. Each of these positions was a credit counterparty transaction (i.e., a repo or swap

contract). Transfer of those positions to the Buffett-led group would require the approval of all the counterparties. Clearly, all of LTCM's counterparties would prefer to have Warren Buffett as a creditor

as opposed to an about-to-be-bankrupt hedge fund. But it was going to be next to impossible to obtain complete approval in one hour.

The partners proposed, as an alternative, that the group make an emergency equity infusion into the fund in return for 90% ownership and the right to kick the partners out as managers. Under this plan, all the financing would stay in place and the third party investors could be redeemed at anytime. Unfortunately, the lawyers were not able to get Buffett back on his satellite phone and no one was prepared to consummate the deal without his approval.

At the end of the day, 14 financial institutions (everyone with the exception of Bear Stearns) agreed to make an emergency \$3.625 billion equity infusion into the fund. The plan was essentially a no-fault bankruptcy where the creditors of a company (in this case, the secured creditors) make an equity investment, cramming down the old equity holders, in order to liquidate the company in an orderly manner.

Why did the Fed orchestrate the bailout? The answer has to do with how the bankruptcy laws are applied with respect to financial firms. When LTCM did the on-the-run versus off-the-run strategy, the risk of the two sides of the trade netted within the fund. But in bankruptcy, each side of the trade liquidates its collateral separately, and sends a bill to LTCM. The risk involved in the position is thus no longer netted at 3.5 bp but is actually 85 bp per side. Although the netted risk of LTCM was \$45 million per day, the gross risk was much larger, more like \$30 million per day with each of 15 counterparties.

As conditions worsened, early in September, the partners had been going around to the counterparties and explaining this enormous potential risk factor in the event of bankruptcy and the large losses that the counterparties would potentially face. They separately asked each dealer to make an equity infusion to shore up LTCM's capital situation. But it was a classic Prisoner's Dilemma problem. No dealer would commit unless everyone else did. It was necessary to get everyone in the same room, so that they would all know the full extent of the exposures and all commit together, and that could not happen until bankruptcy was imminent.

In this event, the private bailout was a success. No counterparty had any losses on their collateral. By the end of the first quarter of 1999, the fund had rallied 25% from its value at the time of the

bailout. At that time third-party investors were paid off. The consortium of banks decided to continue the liquidation at a faster pace and, by December 1999, the liquidation was complete. The banks had no losses and had made a 10% return on their investment.

Investors who had made a \$1 investment at the beginning of 1998 would have seen their investment fall to 8 cents at the time of the bailout, and would have received 10 cents on April 1, 1999. But in its earlier years, LTCM had made high returns and paid out high dividends such that of its 100 investors only 12 actually lost money, and only 6 lost more than \$2 million. The median investor actually had a 19% internal rate of return (IRR) even including the loss. The partners did not fare as well. Their capital was about \$2 billion at the beginning of 1998 and they received no final payout.

Lessons Learned

The LTCM crisis illustrates some of the pitfalls of a VaR-based risk management system (*see Value-at-Risk*), where the risk of the portfolio is determined by the exogenous economic relationships among the trades. During the crisis, all of LTCM's trades moved together with correlations approaching one, even though the trades were economically diverse. It was hard to believe that the returns from US mortgage arbitrage trades would be highly related to LTCM's Japanese warrant and convertible book or highly related to their European government bond spread trades. Yet, during the crisis these correlations all moved toward one, resulting in a failure of diversification and creating enormous risk for the fund.

What was the common thread in all of these trades? It was not that they were economically related, but more that they had similar holders of the trades with common risk tolerances. When these hedge funds and proprietary trading groups at the banks lost money in the Russian crisis they were ordered by senior management to reduce their risk exposures. The trades that they took off were the relative-value trades. As they unwound their positions in the illiquid days of August, the spreads went out further, causing more losses and further unwinds.

This risk might be better classified as endogenous risk, risk that comes about not from the fundamental

economic relationships of the cash flows of the securities but in a crisis through the common movements of the holders of the trades. Prudent risk management practices need to manage the portfolio risk not just for normal times but for crisis times, taking into account the endogenous aspect of risk.

Bubbles and Crashes

The two acclaimed classic books—Galbraith’s “The Great Crash 1929” [40] and Kindleberger’s “Manias, Panics and Crash” [61]—provide the most commonly accepted explanation of the 1929 boom and crash. Galbraith argues that a bubble was formed in the stock market during the rapid economic growth in the 1920s. Both he and Kindleberger, in his extensive historical compendium of financial excesses, emphasize the irrational element—the mania—that induced the public to invest in the bull “overheating” market. The rise in the stock market, according to Galbraith’s account (1954 and 1988, pp. xii-xiii), depended on “the vested interest in euphoria [that] leads men and women, individuals and institutions to believe that all will be better, that they are meant to be richer and to dismiss as intellectually deficient what is in conflict with that conviction.” This eagerness to buy stocks was then fueled by an expansion of credit in the form of brokers’ loans that encouraged investors to become dangerously leveraged. In this respect, Shiller [91] argues that the increase in stock price was driven by irrational euphoria among individual investors, fed by emphatic media, which maximized TV ratings and catered to investor demand for pseudonews.

Kindleberger [61] summarizes his compilation of many historical bubbles as follows.

- The upswing usually starts with an opportunity—new markets, new technologies, or some significant political change—and investors looking for good returns.
- It proceeds through the euphoria of rising prices, particularly of assets, while an expansion of credit inflates the bubble.
- In the manic phase, investors scramble to get out of money and into illiquid investments such as stocks, commodities, real estate, or tulip bulbs: “a larger and larger group of people seeks to become rich without a real understanding of the processes involved.”
- Ultimately, the markets stop rising and people who have borrowed heavily find themselves overstretched. This is “distress”, which generates unexpected failures, followed by “revulsion” or “discredit”.
- The final phase is a self-feeding panic, where the bubble bursts. People of wealth and credit

scramble to unload whatever they have bought at greater and greater losses and cash becomes king.

Although this makes for compelling reading, many questions remain unanswered. There is little consideration about how much fundamentals contributed to the bull market and what might have triggered the speculative mania. Galbraith [40] cited margin buying, the formation of closed-end investment trusts, the transformation of financiers into celebrities, and other qualitative signs of euphoria to support his view. Recent evidence supports the concept of the growth of a social procyclical mood that promotes the attraction for investing in the stock markets by a larger and larger fraction of the population as the bubble grows [88].

Furthermore, Galbraith’s and Kindleberger’s accounts are vague about the causes of the market crash, believing that almost any event could have triggered irrational investors to sell toward the end of bubble, not really explaining the reason for the crash. Instead, they sidestep the thorny question of the occurrence and timing of the crash by focusing on the inevitability of the bubble’s collapse and suggest several factors that could have exploded public confidence and caused prices to plummet. Furthermore, little has been done to identify the precise role of external events in provoking the collapse.

In the words of Shiller [91], a crash is a time when “the investing public en masse capriciously changes its mind.” However, as with the more rational theories, this explanation again leaves unanswered the question of why such tremendous capricious changes in sentiment occur. Alternatively, it amounts to sur-rendering the explanation to the vagaries of “capricious changes”. Other studies have argued that even though fundamentals appeared high in 1929, Fisher [35], for example, argued throughout 1929 and 1930 that the high level of prices in 1929 reflected an expectation that future corporate cash flows would be very high. Fisher believed this expectation to be warranted after a decade of steadily increasing earnings and dividends, of rapidly improving technologies, and of monetary stability. In hindsight, it has become clear that even though fundamentals appeared high in 1929, the stock market rise was clearly excessive. A recent empirical study [25] concludes that the stocks making up the S&P500 composite were priced at least

30% above fundamentals in late summer 1929. White [107] suggests that the 1929 boom cannot be readily explained by fundamentals, represented by expected dividend growth or changes in the equity premium.

While Galbraith's and Kindleberger's classical views have been most often cited by the mass media, they had received little scholarly attention. Since the 1960s, in parallel with the emergence of the efficient-market hypothesis, their position has lost ground among economists and especially among financial economists. More recent works, described at the end of this article, revive their views in the form of quantitative diagnostics.

Efficient-market Hypothesis

The efficient-markets hypothesis (*see Efficient Market Hypothesis*) states that asset prices reflect fundamental value, defined as the discounted sum of expected future cash flows where, in forming expectations, investors "correctly process" all available information. Therefore, in an efficient market, there is "no free lunch": no investment strategy can earn excess risk-adjusted average returns or average returns greater than are warranted for its risk. Proponents of the efficient-markets hypothesis, Friedman and Schwartz [39] and Fama, [34], argue that rational speculative activity would eliminate riskless arbitrage opportunities. Fama ([34], p.38) states that, if there are many sophisticated traders in the market, they may cause these bubbles to burst before they have a chance to really get under way.

However, after years of effort, it has become clear that some basic empirical facts about the stock markets cannot be understood in this framework [106]. The efficient-markets hypothesis entirely lost ground after the burst of the Internet bubble in 2000, providing one of the recent most striking episodes of anomalous price behavior and volatility in one of the most developed capital markets of the world. The movement of Internet stock prices during the late 1990s was extraordinary in many respects. The Internet sector earned over 1000% returns on its public equity in the two-year period from early 1998 through February 2000. The valuations of these stocks began to collapse shortly thereafter and by the end of the same year, they had returned to pre-1998 levels, losing nearly 70% from the peak. The extraordinary returns of 1998–February 2000 had

largely disappeared by the end of 2000. Although in February 2000 the vast majority of Internet-related companies had negative earnings, the Internet sector in the United States was equal to 6% of the market capitalization of all US public companies and 20% of the publicly traded volume of the US stock market [82, 83].

Ofek and Richardson [83] used the financial data from 400 companies in the Internet-related sectors and analyzed to what extent their stock prices differed from their fundamental values estimated by using Miller and Modigliani [79] model for stock valuation [38]. Since almost all companies in the Internet sector had negative earnings, they estimated the (implied) price-to-earnings (P/E) ratios, which are derived from the revenue streams of these firms rather than their earnings that would be read from the 1999 financial data. Their results are striking. Almost 20% of the Internet-related firms have P/E ratios in excess of 1500, while over 50% exceed 500, and the aggregate P/E ratio of the entire Internet sector is 605. Under the assumptions that the aggregate long-run P/E ratio is 20 on average (which is already on the large end member from a historical point of view), the Internet sector would have needed to generate 40.6% excess returns over a 10-year period to justify the P/E ratio of 605 implied in 2000. The vast majority of the implied P/E s are much too high relative to the P/E s usually obtained by firms. By almost any standard, this clearly represented "irrational" valuation levels. These and similar figures led many to believe that this set of stocks was in the midst of an asset price bubble.

From the theoretical point of view, some rational equilibrium asset-pricing models allow for the presence of bubbles, as pointed out for infinite-horizon models in discrete-time setups by Blanchard and Watson [9]. Loewenstein and Willard [70, 71] characterized the necessary and sufficient conditions for the absence of bubbles in complete and incomplete markets equilibria with several types of borrowing constraints and in which agents are allowed to trade continuously. For zero net supply assets, including financial derivatives with finite maturities, they show that bubbles can generally exist and have properties different from their discrete-time, infinite-horizon counterparts. However, Lux and Sornette [73] demonstrated that exogenous rational bubbles are hardly reconcilable with some of the stylized facts of financial data at a very elementary level.

Jarrow *et al.* [53] showed that if financial agents prefer more to less (no dominance assumption), then bubbles in complete markets can only exist which are uniformly integrable martingales, and these can exist with an infinite lifetime. Under these conditions, the put–call parity holds and there are no bubbles in standard call and put options. Their analysis implies that if one believes that asset price bubbles exist, then asset markets must be incomplete. Jarrow *et al.* [54] extend their discussion in [53] to characterize all possible price bubbles in an incomplete market, satisfying the “no free lunch with vanishing risk” and “no dominance” assumptions. Their [54] new theory for bubbles is formulated in terms of different local martingale measures across time, which leads to some testable predictions on derivative pricing in the presence of bubbles.

Heterogeneous Beliefs and Limits to Arbitrage

The collapsing Internet bubble has thrown new light on the old subject and raised the acute question of why rational investors have not moved earlier into the market and driven the Internet stock prices back to their fundamental valuations.

Two conditions are, in general, invoked as being necessary for prices to deviate from the fundamental value. First, there must be some degree of irrationality in the market; that is, investors’ demand for stocks must be driven by something other than fundamentals, such as overconfidence in the future. Second, even if a market has such investors, the general argument is that rational investors will drive prices back to fundamental value. To avoid this, there needs to be some limit on arbitrage. Shleifer and Vishny [92] provide a description for various limits of arbitrage. With respect to the equity market, clearly the most important impediment to arbitrage is short-sales restrictions. Roughly 70% of mutual funds explicitly state (in the Securities and Exchange Commission (SEC) form N-SAR) that they are not permitted to sell short [2]. Seventy-nine percent of equity mutual funds make no use of derivatives whatsoever (either futures or options), suggesting further that funds do not take synthetically short positions [64]. These figures indicate that the vast majority of funds never take short positions.

Recognizing that the world has limited arbitrage and significant numbers of irrational investors,

the finance literature has evolved to increasingly recognize the evidence of deviations from the fundamental value. One important class of theories shows that there can be large movements in asset prices caused by the combined effects of heterogeneous beliefs and short-sales constraints. The basic idea finds its root back to the original capital asset pricing model (CAPM) theories, in particular, to Lintner’s model of asset prices with investors having heterogeneous beliefs [69]. In his model, asset prices are a weighted average of beliefs about asset payoffs with the weights being determined by the investor’s risk aversion and beliefs about asset price covariances. Lintner [69] and many others after him show that widely inflated prices can occur.

Many other asset-pricing models in the spirit of Lintner [69] have been proposed [19, 29, 48, 52, 78, 89]. In these models that assume heterogeneous beliefs and short-sales restrictions, the asset prices are determined at equilibrium to the extent that they reflect the heterogeneous beliefs about payoffs, but short-sales restrictions force the pessimistic investors out of the market, leaving only optimistic investors and thus inflated asset price levels. However, when short-sales restrictions no longer bind investors, then prices fall. This provides a possible account of the bursting of the Internet bubble that developed in 1998–2000. As documented by Ofek and Richardson [83], and by Cochrane [20], typically as much as 80% of Internet-related shares were locked up. This is due to the fact that many Internet companies had gone through recent initial public offerings (IPOs) and regulations impose that shares held by insiders and other pre-IPO equity holders cannot be traded for at least six months after the IPO date. The float of the Internet sector dramatically increased as the lockups of many of these stocks expired. The unlocking of literally hundreds of billions of dollars of shares in the Internet sector in Spring 2000 was equivalent of removing short-sales restrictions. And the collapse of Internet stock prices coincided with a dramatic expansion in the number of publicly tradable shares of Internet companies. Among many others, Hong *et al.* [49] explicitly model the relationship between the number of publicly tradable shares of an asset and the propensity for speculative bubbles to form. So far, the theoretical models based on agents with heterogeneous beliefs facing short-sales restrictions are considered among the most

convincing models to explain the burst of the Internet bubbles.

Another test of this hypothesis on the origin of the 2000 market crash is provided by the search for possible discrepancies between option and stock prices. Indeed, even though it is difficult for rational investors to borrow Internet stocks for short selling due to the lockup period discussed above, they should have been able to construct equivalent synthetic short positions by purchasing puts and writing calls in the option market and either borrowing or lending cash, without the need for borrowing the stocks. The question is now transformed into finding some evidence for the use or the absence of such strategy and the reason for its absence in the latter case. One possible thread is that, if short selling through option positions was difficult or impractical, prices in the stock and options markets should decouple [67]. Using a sample of closing bid and ask prices for 9026 option pairs for three days in February 2000 along with closing trade prices for the underlying equities, Ofek and Richardson [83] find that 36% of the Internet stocks had put–call parity violations as compared to only 23.8% of the other stocks. One reason for put–call parity violations may be that short-sale restrictions prevent arbitrage from equilibrating option and stock prices. Hence, one interpretation of the finding that there are more put–call parity violations for Internet stocks is that short-sale constraints are more frequently binding for Internet stocks. Furthermore, Ofek *et al.* [84] provide a comprehensive comparison of the prices of stocks and options, using closing options quotes and closing trades on the underlying stock for July 1999 through November 2001. They find that there are large differences between the synthetic stock price and the actual stock price, which implies the presence of apparent arbitrage opportunities involving selling actual shares and buying synthetic shares. They interpret their findings as evidence that short-sale constraints provide meaningful limits to arbitrage that can allow prices of identical assets to diverge.

By defining a bubble as a price process that, when discounted, is a local martingale under the risk-neutral measure but not a martingale, Cox and Hobson [21] provide a complementary explanation for the failure of put–call parity. Intuitively, the local martingale model views a bubble as a stopped stochastic process for which the expectation exhibits a discontinuity when it ends. It can then be shown

that several standard results fail for local martingales: put–call parity does not hold, the price of an American call exceeds that of a European call, and call prices are no longer increasing in maturity (for a fixed strike).

Thus, it would seem that the issue of the origin of the 2000 crash is settled. However, Battalio and Schultz [6] arrive at the opposite conclusion, using proprietary intraday option trade and quote data generated in the days surrounding the collapse of the Internet bubble. They find that the general public could cheaply short synthetically using options, and this information could have been transmitted to the stock market, in line with the absence of evidence that synthetic stock prices diverged from actual stock prices. The difference between the work of Ofek and Richardson [83] and Ofek *et al.* [84], on the one hand, and Battalio and Schultz [6], on the other, is that the former used closing option quotes and last stock trade prices from the OptionMetrics Ivy database. As pointed out by Battalio and Schultz [6], OptionMetrics matches closing stock trades that occurred no later than 4:00 pm, and perhaps much earlier, with closing option quotes posted at 4:02 pm. Furthermore, option market makers that post closing quotes on day t are not required to trade at those quotes on day $t + 1$. Likewise, dealers and specialists in the underlying stocks have no obligation to execute incoming orders at the price of the most recent transaction. Hence, closing option quotes and closing stock prices obtained from the OptionMetrics database do not represent contemporaneous prices at which investors could have simultaneously traded. To address this problem, Battalio and Schultz [6] use a unique set of intraday option price data. They first ensure that the synthetic and the actual stock prices that they compare are synchronous, and then, they discard quotes that, according to exchange rules, are only indicative of the prices at which liquidity demanders could have traded. They find that almost all of the remaining apparent put–call parity violations disappear when they discard locked or crossed quotes and quotes from fast options markets. In other words, the apparent arbitrage opportunities almost always arise from quotes upon which investors could not actually trade. Battalio and Schultz [6] conclude that short-sale constraints were not responsible for the high prices of Internet stocks at the peak of the bubble and that small investors could have

sold short synthetically using options, and this information would have been transmitted to the stock market. The fact that investors did not take advantage of these opportunities to profit from overpriced Internet stocks suggests that the overpricing was not as obvious then as it is now, with the benefit of hindsight. Schultz [90] provides additional evidence that contemporaneous lockup expirations and equity offerings do not explain the collapse of Internet stocks because the stocks that were restricted to a fixed supply of shares by lockup provisions actually performed worse than stocks with an increasing supply of shares. This shows that current explanations for the collapse of Internet stocks are incomplete.

Riding Bubbles

One cannot understand crashes without knowing the origin of bubbles. In a nutshell, speculative bubbles are caused by “precipitating factors” that change public opinion about markets or that have an immediate impact on demand and by “amplification mechanisms” that take the form of price-to-price feedback, as stressed by Shiller [91]. Consider the example of a housing-market bubble. A number of fundamental factors can influence price movements in housing markets. The following characteristics have been shown to influence the demand for housing: demographics, income growth, employment growth, changes in financing mechanisms, interest rates, as well as changes in the characteristics of the geographic location such as accessibility, schools, or crime, to name a few. On the supply side, attention has been paid to construction costs, the age of the housing stock, and the industrial organization of the housing market. The elasticity of supply has been shown to be a critical factor in the cyclical behavior of home prices. The cyclical process that we observed in the 1980s in those cities experiencing boom-and-bust cycles was caused by the general economic expansion, best proxied by employment gains, which drove up the demand. In the short run, those increases in demand encountered an inelastic supply of housing and developable land, inventories of for-sale properties shrank, and vacancy declined. As a consequence, prices accelerated. This provided an amplification mechanism as it led buyers to anticipate further gains, and the

bubble was born. Once prices overshoot or supply catches up, inventories begin to rise, time on the market increases, vacancy rises, and price increases slow down, eventually encountering downward stickiness. The predominant story about home prices is always the prices themselves [91, 93]; the feedback from initial price increases to further price increases is a mechanism that amplifies the effects of the precipitating factors. If prices are going up rapidly, there is much word-of-mouth communication, a hallmark of a bubble. The word of mouth can spread optimistic stories and thus help cause an overreaction to other stories, such as ones about employment. The amplification can work on the downside as well.

Hedge funds are among the most sophisticated investors, probably closer to the ideal of “rational arbitrageurs” than any other class of investors. It is therefore particularly telling that successful hedge-fund managers have been repeatedly reported to ride rather than attack bubbles, suggesting the existence of mechanisms that entice rational investors to surf bubbles rather than attempt to arbitrage them. However, the evidence may not be that strong and could even be circular, since only successful hedge-fund managers would survive a given 2–5 year period, opening the possibility that the mentioned evidence could result in large part from a survival bias [14, 44]. Keeping this in mind, we now discuss two classes of models, which attempt to justify why sophisticated “rational” traders would be willing to ride bubbles. These models share a common theme: rational investors try to ride bubbles, and the incentive to ride the bubble stems from predictable “sentiment”—anticipation of continuing bubble growth [1] and predictable feedback trader demand [26, 27]. An important implication of these theories is that rational investors should be able to reap gains from riding a bubble at the expense of less-sophisticated investors.

Positive Feedback Trading by Noise Traders

The term *noise traders* was introduced first by Kyle [65] and Black [8] to describe irrational investors. Thereafter, many scholars exploited this concept to extend the standard models by introducing the simplest possible heterogeneity in terms

of two interacting populations of rational and irrational agents. One can say that the one-representative-agent theory is being progressively replaced by a two-representative-agents theory, analogously to the progress from the one-body to the two-body problems in astronomy.

De Long *et al.* [26, 27] introduced a model of market bubbles and crashes, which exploits this idea of the possible role of noise traders in the development of bubbles as a possible mechanism for why asset prices may deviate from the fundamentals over rather long time periods. Their inspiration came from the observation of successful investors such as George Soros, who reveal that they often exploit naive investors following positive feedback strategies or momentum investment strategies. Positive feedback investors are those who buy securities when prices rise and sell when prices fall. In the words of Jegadeesh and Titman [55], positive feedback investors are buying winners and selling losers. In a description of his own investment strategy, Soros [101] stresses that the key to his success was not to counter the irrational wave of enthusiasm that appears in financial markets, but rather to *ride this wave* for a while and sell out much later. The model of De Long *et al.* [26, 27] assumes that when rational speculators receive good news and trade on this news, they recognize that the initial price increase will stimulate buying by noise traders who will follow positive feedback trading strategies with a delay. In anticipation of these purchases, rational speculators buy more today, and so drive prices up today higher than fundamental news warrants. Tomorrow, noise traders buy in response to increase in today's price and so keep prices above the fundamentals. The key point is that trading between rational arbitrageurs and positive feedback traders gives rise to bubble-like price patterns. In their model, rational speculators destabilize prices because their trading triggers positive feedback trading by other investors. Positive feedback trading reinforced by arbitrageurs' jumping on the bandwagon leads to a positive autocorrelation of returns at short horizons. Eventually, selling out or going short by rational speculators will pull the prices back to the fundamentals, entailing a negative autocorrelation of returns at longer horizons. In summary, De Long *et al.* [26, 27] model suggests the coexistence of intermediate-horizon momentum and long-horizon reversals in stock returns.

Their work was followed by a number of behavioral models based on the idea that trend chasing by one class of agents produces momentum in stock prices [5, 22, 50]. The most influential empirical evidence on momentum strategies came from the work of Jegadeesh and Titman [55, 56], who established that stock returns exhibit momentum behavior at intermediate horizons. Strategies that buy stocks that have performed well in the past and sell stocks that have performed poorly in the past generate significant positive returns over 3- to 12-month holding periods. De Bondt and Thaler [24] documented long-term reversals in stock returns. Stocks that perform poorly in the past perform better over the next 3–5 years than stocks that perform well in the past. These findings present a serious challenge to the view that markets are semistrong-form efficient.

In practice, do investors engage in momentum trading? A growing number of empirical studies address momentum trading by investors, with somewhat conflicting results. Lakonishok *et al.* [66] analyzed the quarterly holdings of a sample of pension funds and found little evidence of momentum trading. Grinblatt *et al.* [45] examined the quarterly holdings of 274 mutual funds and found that 77% of the funds in their sample engaged in momentum trading [105]. Nofsinger and Sias [81] examined total institutional holdings of individual stocks and found evidence of intraperiod momentum trading. Using a different sample, Gompers and Metrick [41] investigated the relationship between institutional holdings and lagged returns and concluded that once they controlled for the firm size, there was no evidence of momentum trading. Griffin *et al.* [43] reported that, on a daily and intraday basis, institutional investors engaged in trend chasing in NASDAQ 100 stocks. Finally, Badrinath and Wahal [4] documented the equity trading practices of approximately 1200 institutions from the third quarter of 1987 through the third quarter of 1995. They decomposed trading by institutions into (i) the initiation of new positions (entry), (ii) the termination of previous positions (exit), and (iii) the adjustments to ongoing holdings. Institutions were found to act as momentum traders when they enter stocks but as contrarian traders when they exit or make adjustments to ongoing holdings. Badrinath and Wahal [4] found significant differences in trading practices among different types of institutions. These studies are limited in their ability to capture the full range of trading

practices, in part because they focus almost exclusively on the behavior of institutional investors. In summary, many experimental studies and surveys suggest that positive feedback trading exists in greater or lesser degrees.

Synchronization Failures among Rational Traders

Abreu and Brunnermeier [1] propose a completely different mechanism justifying why rational traders ride rather than arbitrage bubbles. They consider a market where arbitrageurs face synchronization risk and, as a consequence, delay usage of arbitrage opportunities. Rational arbitrageurs are supposed to know that the market will eventually collapse. They know that the bubble will burst as soon as a sufficient number of (rational) traders will sell out. However, the dispersion of rational arbitrageurs' opinions on market timing and the consequent uncertainty on the synchronization of their sell-off are delaying this collapse, allowing the bubble to grow. In this framework, bubbles persist in the short and intermediate term because short sellers face synchronization risk, that is, uncertainty regarding the timing of the correction. As a result, arbitrageurs who conclude that other arbitrageurs are yet unlikely to trade against the bubble find it optimal to ride the still growing bubble for a while.

Like other institutional investors, hedge funds with large holdings in US equities have to report their quarterly equity positions to the SEC on Form 13F. Brunnermeier and Nagel [15] extracted hedge-fund holdings from these data, including those of well-known managers such as Soros, Tiger, Tudor, and others in the period from 1998 to 2000. They found that, over the sample period 1998–2000, hedge-fund portfolios were heavily tilted toward highly priced technology stocks. The proportion of their overall stock holdings devoted to this segment was higher than the corresponding weight of technology stocks in the market portfolio. In addition, the hedge funds in their sample skillfully anticipated price peaks of individual technology stocks. On a stock-by-stock basis, hedge funds started cutting back their holdings before prices collapsed, switching to technology stocks that still experienced rising prices. As a result, hedge-fund managers captured the upturn, but avoided much of the downturn. This

is reflected in the fact that hedge funds earned substantial excess returns in the technology segment of the NASDAQ.

Complex Systems Approach to Bubbles and Crashes

Bhattacharya and Yu [7] provide a summary of recent efforts to expand on the above concepts, in particular, to address the two main questions of (i) the cause(s) of bubbles and crashes and (ii) the possibility to diagnose them *ex ante*. Many financial economists recognize that positive feedbacks and, in particular, herding are the key factors for the growth of bubbles. Herding can result from a variety of mechanisms, such as anticipation by rational investors of noise traders' strategies [26, 27], agency costs and monetary incentives given to competing fund managers [23] sometimes leading to the extreme Ponzi schemes [28], rational imitation in the presence of uncertainty [88], and social imitation.

The Madoff Ponzi scheme is a significant recent illustration, revealed by the unfolding of the financial crisis that started in 2007 [97]. It is the world's biggest fraud allegedly perpetrated by long-time investment adviser Bernard Madoff, arrested on December 11, 2008 and sentenced on June 29, 2009 to 150 years in prison, the maximum allowed. His fraud led to 65 billion US dollars losses that caused reverberations around the world as the list of victims included many wealthy private investors, charities, hedge funds, and major banks in the United States, Europe, and Asia. The Madoff Ponzi scheme surfed on the general psychology, characterizing the first decade of the twenty-first century, of exorbitant unsustainable expected financial gains. It is a remarkable illustration of the problem of implementing sound risk management, due diligence processes, and of the capabilities of the SEC, the US markets watchdog, when markets are booming and there is a general sentiment of a new economy and new financial era, in which old rules are believed not to apply anymore [75]. Actually, the Madoff Ponzi scheme is only the largest of a surprising number of other Ponzi schemes revealed by the financial crisis in many different countries (see accounts from village.albourne.com).

Discussing social imitation is often considered off-stream among financial economists but warrants

some scrutiny, given its pervasive presence in human affairs. On the question of the *ex ante* detection of bubbles, Gurkaynak [46] summarizes the dismal state of the econometric approach, stating that the “econometric detection of asset price bubbles cannot be achieved with a satisfactory degree of certainty. For each paper that finds evidence of bubbles, there is another one that fits the data equally well without allowing for a bubble. We are still unable to distinguish bubbles from time-varying or regime-switching fundamentals, while many small sample econometrics problems of bubble tests remain unresolved.” The following discusses an arguably off-stream approach that, by using concepts and tools from the theory of complex systems and statistical physics, suggests that *ex ante* diagnostic and partial predictability might be possible [93].

Social Mimetism, Collective Phenomena, Bifurcations, and Phase Transitions

Market behavior is the aggregation of the individual behavior of the many investors participating in it. In an economy of traders with completely rational expectations and the same information sets, no bubbles are possible [104]. Rational bubbles can, however, occur in infinite-horizon models [9], with dynamics of growth and collapse driven by noise traders [57, 59]. However, the key issue is to understand by what detailed mechanism the aggregation of many individual behaviors can give rise to bubbles and crashes. Modeling social imitation and social interactions requires using approaches, little known to financial economists, that address the fundamental question of how global behaviors can emerge at the macroscopic level. This extends the representative agent approach, but it also goes well beyond the introduction of heterogeneous agents. A key insight from statistical physics and complex systems theory is that systems with a large number of interacting agents, open to their environment, self-organize their internal structure and their dynamics with novel and sometimes surprising “emergent” out-of-equilibrium properties. A central property of a complex system is the possible occurrence and coexistence of many large-scale collective behaviors with a very rich structure, resulting from the repeated nonlinear interactions among its constituents.

How can this help address the question of what is/are the cause(s) of bubbles and crashes? The crucial insight is that a system, made of competing investors subjected to the myriad of influences, both exogenous news and endogenous interactions and reflexivity, can develop into endogenously self-organized self-reinforcing regimes, which would qualify as bubbles, and that crashes occur as a global self-organized transition. Mathematicians refer to this behavior as a *bifurcation* or more specifically as a *catastrophe* [103]. Physicists call these phenomena *phase transitions* [102]. The implication of modeling a market crash as a bifurcation is to solve the question of what makes a crash: in the framework of bifurcation theory (or phase transitions), sudden shifts in behavior arise from small changes in circumstances, with qualitative changes in the nature of the solutions that can occur abruptly when the parameters change smoothly. A minor change of circumstances, of interaction strength, or heterogeneity may lead to a sudden and dramatic change, such as during an earthquake and a financial crash.

Most approaches for explaining crashes search for possible mechanisms or effects that operate at very short timescales (hours, days, or weeks at most). According to the “bifurcation” approach, the underlying cause of the crash should be found in the preceding months and years, in the progressively increasing buildup of market cooperativity, or effective interactions between investors, often translated into accelerating ascent of the market price (the bubble). According to this “critical” point of view, the specific manner in which prices collapsed is not the most important problem: a crash occurs because the market has entered an unstable phase and any small disturbance or process may reveal the existence of the instability.

Ising Models of Social Imitation and Phase Transitions

Perhaps the simplest and historically most important model describing how the aggregation of many individual behaviors can give rise to macroscopic out-of-equilibrium dynamics such as bubbles, with bifurcations in the organization of social systems due to slight changes in the interactions, is the Ising model [16, 80]. In particular, Orléan [85, 86] captured the paradox of combining rational and imitative behavior under the name *mimetic rationality*, by developing

models of mimetic contagion of investors in the stock markets, which are based on irreversible processes of opinion forming. Roehner and Sornette [88], among others, showed that the dynamical updating rules of the Ising model are obtained in a natural way as the optimal strategy of rational traders with limited information who have the possibility to make up for their lack of information *via* information exchange with other agents within their social network. The Ising model is one of the simplest models describing the competition between the ordering force of imitation or contagion and the disordering impact of private information or idiosyncratic noise (see [77] for a technical review).

Starting with a framework suggested by Blume [10, 11], Brock [12], Durlauf [30–33], and Phan *et al.* [87] summarize the formalism starting with different implementation of the agents' decision processes whose aggregation is inspired from statistical mechanics to account for social influence in individual decisions. Lux and Marchesi [72], Brock and Hommes [13], Kaizoji [60], and Kirman and Teyssiere [63] also developed related models in which agents' successful forecasts reinforce the forecasts. Such models have been found to generate swings in opinions, regime changes, and long memory. An essential feature of these models is that agents are wrong for some of the time, but whenever they are in the majority they are essentially right. Thus, they are not systematically irrational [62]. Sornette and Zhou [99] show how Bayesian learning added to the Ising model framework reproduces the stylized facts of financial markets. Harras and Sornette [47] show how overlearning from lucky runs of random news in the presence of social imitation may lead to endogenous bubbles and crashes.

These models allow one to combine the questions on the cause of both bubbles and crashes, as resulting from the collective emergence of herding *via* self-reinforcing imitation and social interactions, which are then susceptible to phase transitions or bifurcations occurring under minor changes in the control parameters. Hence, the difficulty in answering the question of “what causes a bubble and a crash” may, in this context, be attributed to this distinctive attribute of a dynamical out-of-equilibrium system to exhibit bifurcation behavior in its dynamics. This line of thought has been pursued by Sornette and his coauthors, to propose a novel operational diagnostic of bubbles.

V-3 Bubble as Superexponential Price Growth, Diagnostic, and Prediction

Bubbles are often defined as exponentially explosive prices, which are followed by a sudden collapse. As summarized, for instance, by Gurkaynak [46], the problem with this definition is that any exponentially growing price regime—that one would call a bubble—can be also rationalized by a fundamental valuation model. This is related to the problem that the fundamental price is not directly observable, giving no strong anchor to understand observed prices. This was exemplified during the last Internet bubble by fundamental pricing models, which incorporated real options in the fundamental valuation, justifying basically any price. Mauboussin and Hiler [76] were among the most vocal proponents of the proposition, offered close to the peak of the Internet bubble that culminated in 2000, that better business models, the network effect, first-to-scale advantages, and real options effect could account rationally for the high prices of dot-com and other New Economy companies. These interesting views expounded in early 1999 were in synchrony with the bull market of 1999 and preceding years. They participated in the general optimistic view and added to the strength of the herd. Later, after the collapse of the bubble, these explanations seemed less attractive. This did not escape the US Federal Reserve chairman Greenspan [42], who said: “Is it possible that there is something fundamentally new about this current period that would warrant such complacency? Yes, it is possible. Markets may have become more efficient, competition is more global, and information technology has doubtless enhanced the stability of business operations. But, regrettably, history is strewn with visions of such new eras that, in the end, have proven to be a mirage. In short, history counsels caution.” In this vein, the buzzword “new economy” so much used in the late 1990s was also in use in the 1960s during the “tronic boom” also followed by a market crash and during the bubble of the late 1920s before the October 1929 crash. In the latter case, the “new” economy was referring to firms in the utility sector. It is remarkable how traders do not learn the lessons of their predecessors.

A better model derives from the mechanism of positive feedbacks discussed above, which generically gives rise to faster-than-exponential growth of

price (termed as *superexponential*) [95, 96]. An exponential growing price is characterized by a constant expected growth rate. The geometric random walk is the standard stochastic price model embodying this class of behaviors. A superexponential growing price is such that the growth rate grows itself as a result of positive feedbacks of price, momentum, and other characteristics on the growth rate [95]. As a consequence of the acceleration, the mathematical models generalizing the geometric random walk exhibit so-called finite-time singularities. In other words, the resulting processes are not defined for all times: the dynamics has to end after a finite life and to transform into something else. This captures well the transient nature of bubbles, and the fact that the crashes ending the bubbles are often the antechambers to different market regimes.

Such an approach may be thought of, at first sight, to be inadequate or too naive to capture the intrinsic stochastic nature of financial prices, whose null hypothesis is the geometric random walk model [74]. However, it is possible to generalize this simple deterministic model to incorporate nonlinear positive feedback on the stochastic Black–Scholes model, leading to the concept of stochastic finite-time singularities [3, 36, 37, 51, 95]. Much work still needs to be done on this theoretical aspect.

In a series of empirical papers, Sornette and his collaborators have used this concept to empirically test for bubbles and prognosticate their demise often in the form of crashes. Johansen and Sornette [58] provide perhaps the most inclusive series of tests of this approach. First, they identify the most extreme cumulative losses (drawdowns) in a variety of asset classes, markets, and epochs, and show that they belong to a probability density distribution, which is distinct from the distribution of 99% of the smaller drawdowns (the more “normal” market regime). These drawdowns can thus be called *outliers* or *kings* [94]. Second, they show that, for two-thirds of these extreme drawdowns, the market prices followed a superexponential behavior before their occurrences, as characterized by the calibration of the power law with a finite-time singularity.

This provides a systematic approach to diagnose for bubbles *ex ante*, as shown in a series of real-life tests [98, 100, 108–111]. Although this approach has enjoyed a large visibility in the professional financial community around the world (banks, mutual funds, hedge funds, investment houses, etc.), it has not yet

received the attention from the academic financial community that it perhaps deserves given the stakes. This is probably due to several factors, which include the following: (i) the origin of the hypothesis coming from analogies with complex critical systems in physics and the theory of complex systems, which constitutes a well-known obstacle to climb the ivory towers of standard financial economics; (ii) the non-standard (from an econometric viewpoint) formulation of the statistical tests performed until present (in this respect, see the attempts in terms of a Bayesian analysis of log-periodic power law (LPPL) precursors [17] to focus on the time series of returns instead of prices, and of regime-switching model of LPPL [18]), (iii) the nonstandard expression of some of the mathematical models underpinning the hypothesis; and (iv) perhaps an implicit general belief in academia that forecasting financial instabilities is inherently impossible. Lin *et al.* [68] have recently addressed problem (ii) by combining a mean-reverting volatility process and a stochastic conditional return, which reflects nonlinear positive feedbacks and continuous updates of the investors’ beliefs and sentiments. When tested on the S&P500 US index from January 3, 1950 to November 21, 2008, the model correctly identifies the bubbles that ended in October 1987, in October 1997, in August 1998, and the information and communication technologies (ICT) bubble that ended in the first quarter of 2000. Using Bayesian inference, Lin *et al.* [68] find a very strong statistical preference for their model compared with a standard benchmark, in contradiction with Chang and Feigenbaum [17], who used a unit-root model for residuals.

V-4 Bubbles and the Great Financial Crisis of 2007

It is appropriate to end this article with some comments on the relationship between the momentous financial crisis and bubbles. The financial crisis, which started with an initially well-defined epicenter focused on mortgage-backed securities (MBS), has been cascading into a global economic recession, whose increasing severity and uncertain duration are continuing to lead to massive losses and damage for billions of people. At the time of writing (July 2009), the world still suffers from a major financial crisis that has transformed into the worst economic recession since the Great Depression, perhaps on its way

to surpass it. Heavy central bank interventions and government spending programs have been launched worldwide and especially in the United States and Europe, with the hope to unfreeze credit and bolster consumption.

The current financial crisis is a perfect illustration of the major role played by financial bubbles. We refer to the analysis, figures, and references in [97], which articulate a general framework, suggesting that the fundamental cause of the unfolding financial and economic crisis is the accumulation of five bubbles:

1. the “new economy” ICT bubble that started in the mid-1990s and ended with the crash of 2000;
2. the real-estate bubble launched in large part by easy access to a large amount of liquidity as a result of the active monetary policy of the US Federal Reserve lowering the fed rate from 6.5% in 2000 to 1% in 2003 and 2004 in a successful attempt to alleviate the consequence of the 2000 crash;
3. the innovations in financial engineering with the collateralized debt obligations (CDOs) and other derivatives of debts and loan instruments issued by banks and eagerly bought by the market, accompanying and fueling the real-estate bubble;
4. the commodity bubble(s) on food, metals, and energy; and
5. the stock market bubble that peaked in October 2007.

These bubbles, by their interplay and mutual reinforcement, have led to the illusion of a “perpetual money machine”, allowing financial institutions to extract wealth from an unsustainable artificial process. This realization calls to question the soundness of many of the interventions to address the recent liquidity crisis that tend to encourage more consumption.

TAISEI KAIZOJI & DIDIER SORNETTE

Ross, Stephen

The central focus of the work of Ross (1944–) has been to tease out the consequences of the assumption that all riskless arbitrage opportunities have already been exploited and none remain. The empirical relevance of the no arbitrage assumption is especially high in the area of financial markets for two simple reasons: there are many actors actively searching for arbitrage opportunities, and the exploitation of such opportunities is relatively costless. For finance, therefore, the principle of no arbitrage is not merely a convenient assumption that makes it possible to derive clean theoretical results but even more an idealization of observable empirical reality, and a characterization of the deep and simple structure underlying multifarious surface phenomena. For one whose habits of mind were initially shaped by the methods of natural science, specifically physics as taught by Richard Feynman (B.S. California Institute of Technology, 1965), finance seemed to be an area of economics where a truly scientific approach was possible.

It was exposure to the Black–Scholes option pricing theory, when Ross was starting his career as an assistant professor at the University of Pennsylvania, that first sparked his interest in the line of research that would occupy him for the rest of his life. If the apparently simple and eminently plausible assumption of no arbitrage could crack the problem of option pricing, perhaps it could crack other problems in finance as well. In short order, Ross produced what he later called the *fundamental theorem of asset pricing* [7, p. 101], which linked the absence of arbitrage with the existence of a positive linear pricing rule [12, 15] (see **Fundamental Theorem of Asset Pricing**).

Perhaps the most important practical implication of this theorem is that it is possible to price assets that are not yet traded simply by reference to the price of assets that are already traded, and to do so without the need to invoke any particular theory of asset pricing. This opened the possibility of creating new assets, such as options, that would in practical terms “complete” markets, and so help move the economy closer to the ideal efficient frontier characterized by Kenneth Arrow (see **Arrow, Kenneth**) as a complete set of markets for state-contingent securities [11]. Here, in the abstract, is

arguably the vision that underlies the entire field of financial engineering.

The general existence of a linear pricing rule has further implications that Ross would later group together in what he called the *pricing rule representation theorem* [7, p. 104]. Most important for practical purposes is the existence of positive risk-neutral probabilities and an associated riskless rate of interest, a feature first noted in [4, 5]. It is this general feature that makes it possible to model option prices by treating the underlying stock price as a binomial random variable in discrete time, as first introduced by Cox *et al.* [6] in an approach that is now ubiquitous in industry practice. It is this same general feature that makes it possible to characterize asset prices generally as following a martingale under the equivalent martingale measure [9], a characterization that is also now routine in financial engineering practice.

What is most remarkable about these consequences of the no arbitrage point of view is how little economics has to do with it. Ross, a trained economist (Harvard, PhD, 1969), might well have built a rather different career, perhaps in the area of agency theory where he made one of the early seminal contributions [10], but once he found finance he never looked back. (His subsequent involvement in agency theory largely focused on financial intermediation in a world with no arbitrage, as in [14, 18].)

When Ross was starting his career, economists had already begun making inroads into finance, and one of the consequences was the Sharpe–Lintner capital asset pricing model (CAPM) (see **Modern Portfolio Theory**). Ross [16] reinterpreted the CAPM as a possible consequence of no arbitrage and then proposed his own arbitrage pricing theory [13] as a more general consequence that would be true whenever asset prices were generated by a linear factor model such as

$$R_i = E_i + \sum \beta_{ij} f_j + \varepsilon_i, \quad i = 1, \dots, n \quad (1)$$

where E_i is the expected return on asset i , f_i is an exogenous systematic factor, and ε_i is the random noise.

In such a world, it follows from no arbitrage that the expected return on asset i , in excess of the risk-free rate of return r , is equal to a linear combination

of the factor loadings β_{ij} :

$$E_i - r = \Sigma \lambda_j \beta_{ij} \quad (2)$$

This is the APT generalization of the CAPM security market line that connects the mean–variance of the market (r_M , σ_M) to that of the risk-free asset (r , 0).

It also follows that the optimal portfolio choice for any agent can be characterized as a weighted sum of n mutual funds, one for each factor. This is the APT generalization of the CAPM two-fund separation theorem, and unlike CAPM it does not depend on any special assumptions about either utility functions or the stochastic processes driving asset returns. In a certain sense, it does not depend on economics.

We can understand the work of Cox *et al.* [1–3] as an attempt to connect the insights of no arbitrage back to economic “fundamentals”. “In work on contingent claims analysis, such as option pricing, it is common, and to a first approximation reasonable, to insist only on a partial equilibrium between the prices of the primary and derivative assets. For something as fundamental as the rate of interest, however, a general equilibrium model is to be preferred” [1, p. 773]. They produce a general equilibrium model driven by a k -dimensional vector of state variables, but are forced to specialize the model considerably in order to achieve definite results for the dynamics of interest rates and the term structure. Here, more than anywhere else in Ross’s wide-ranging work, we see the tension between the methodologies of economics and finance. It is this experience, one supposes, that lies behind his subsequent defense of the “isolated and eccentric tradition” that is unique to finance [17, p. 34]. The tradition to which he refers is the practice of approaching financial questions from the perspective of no arbitrage, without the apparatus of utility and production functions and without demand and supply.

Not content with having established the core principles and fundamental results of the no arbitrage approach to finance, Ross devoted his subsequent career to making sure that the significance and wide applicability of these results was appreciated by both academicians and practitioners. Toward that end, his own voluminous writings have been multiplied by the work of the many students whom he trained at the University of Pennsylvania, then Yale, and then MIT [8].

PERRY MEHRLING

Fisher, Irving

The American economist Irving Fisher (born 1867, died 1947) advanced the use of formal mathematical and statistical techniques in economics and finance, both in his own pioneering research in monetary and capital theory and in his roles as a mentor to a handful of talented doctoral students and as founding president of the Econometric Society. As an undergraduate and a graduate student at Yale University, Fisher studied with the physicist J. Willard Gibbs and the economist and sociologist William Graham Sumner. Fisher's 1891 doctoral dissertation in economics and mathematics, *Mathematical Investigations in the Theory of Value and Prices* (reprinted in [12], Vol. 1), was the first North American use of general equilibrium analysis—indeed, an independent rediscovery of general equilibrium, because Fisher did not read the works of Léon Walras and F.Y. Edgeworth until his thesis was nearly completed. To accompany this thesis, Fisher constructed a hydraulic mechanism to simulate the determination of equilibrium prices and quantities, a remarkable achievement in the days before electronic computers (see Brainard and Scarf in [5] and Schwalbe in [14]). Initially appointed to teach mathematics at Yale, Fisher soon switched to political economy, teaching at Yale until he retired in 1935. Stricken with tuberculosis in 1898, Fisher was on leave for three years, and did not resume a full teaching load until 1903. This ordeal turned Fisher into a relentless crusader for healthier living and economic reforms, dedicated to improving the world and confident of overcoming adversity and daunting obstacles [1, 5, 14]. As a scientific economist and as a reformer, Fisher was a brilliant and multifaceted innovator, but he never managed to pull his ideas together in a grand synthesis.

In *The Nature of Capital and Income*, Fisher [7] popularized the concept of net present value, viewing capital as the present discounted value of an expected income stream. Controversially, Fisher excluded saving from his definition of income, and advocated a spending tax instead of a tax on income as usually defined. Since saving is the acquisition of assets whose market value is the net present value of the expected taxable income from owning the assets, a tax on income (as usually defined) would involve double taxation and would introduce a distortion

favoring consumption at the expense of saving, a view now increasingly held by economists. Fisher [7] also discussed the pricing and allocation of risk in financial markets, using a “coefficient of caution” to represent subjective attitudes to risk tolerance [2, 3, 18]. In *The Rate of Interest*, Fisher [8] drew on the earlier work of John Rae and Eugen von Böhm-Bawerk to examine how intertemporal allocation and the real interest rate depend on impatience (time preference) and opportunity to invest (expected rate of return over cost). He illustrated this analysis with the celebrated “Fisher diagram” showing optimal smoothing of consumption over two periods. According to the “Fisher separation theorem,” the time pattern of consumption is independent of the time pattern of income (assuming perfect credit markets), because the net present value of expected lifetime income is the relevant budget constraint for consumption and saving decisions, rather than income in a particular period. Fisher's analysis of consumption smoothing across time periods provided the basis for later permanent-income and life-cycle models of consumption, and was extended by others to consumption smoothing across possible states of the world. John Maynard Keynes later identified his concept of the marginal efficiency of capital with Fisher's rate of return over costs.

Fisher's *Appreciation and Interest* [6] presented the “Fisher equation,” decomposing nominal interest into real interest and expected inflation, formalizing and expounding an idea that had been briefly noted by, among others, John Stuart Mill and Alfred Marshall. With i as the nominal interest rate, j as the real interest rate, and a as the expected rate of appreciation of the purchasing power of money ([6] appeared at the end of two decades of falling prices),

$$(1 + j) = (1 + a)(1 + i) \quad (1)$$

in Fisher's notation. This analysis of the relationship between interest rates expressed in two different standards (money and goods, gold and silver, dollars and pounds sterling) led Fisher [6] to uncovered interest parity (the difference between nominal interest rates in two currencies is the expected rate of change of the exchange rate) and to a theory of the term structure of interest rates as reflecting expectations about future changes in the purchasing power of money. In later work (see [12], Vol. 9), Fisher correlated nominal interest with a distributed lag of

past price level changes, deriving expected inflation adaptively from past inflation. Distributed lags were introduced into economics by Fisher, who was also among the first economists to use correlation analysis. Long after Fisher's death, his pioneering 1926 article [10], correlating unemployment with a distributed lag of inflation, was reprinted in 1973, under the title "I Discovered the Phillips Curve."

In *The Purchasing Power of Money*, Fisher [13] upheld the quantity theory of money, arguing that changes in the quantity of money affect real output and real interest during adjustment periods of up to 10 years, but affect only nominal variables in the long run. He extended the quantity theory's equation of exchange to include bank deposits:

$$MV + M'V' = PT \quad (2)$$

where M is currency, M' bank deposits, V and V' the velocities of circulation of currency and bank deposits, respectively, P the price level, and T an index of the volume of transactions. Fisher attributed economic fluctuations to the slow adjustment of nominal interest to monetary shocks, resulting from what he termed "*the money illusion*" in the title of a 1928 book (in [12], Vol. 8). The economy would be stable if, instead of pegging the dollar price of gold, monetary policy followed Fisher's "compensated dollar" plan of regularly varying the price of gold to target an index number of prices. Inflation targeting is a modern version of Fisher's proposed price level target (without attempting a variable peg of the price of gold, which would have made Fisher's plan vulnerable to speculative attacks). Failing to persuade governments to stabilize the purchasing power of money, Fisher attempted to neutralize the effects of price level changes by advocating the creation of indexed financial instruments, persuading Rand Kardex (later Remington Rand) to issue the first indexed bond (see [12], Vol. 8). Fisher tried to educate the public against money illusion, publishing a weekly index of wholesale prices calculated by an index number institute operating out of his house in New Haven, Connecticut. Indexed bonds, the compensated dollar, statistical verification of the quantity theory, and eradication of money illusion all called for a measure of the price level. In *The Making of Index Numbers*, Fisher [9] argued that a simple formula, the geometric mean of the Laspeyres (base-year weighted) index and the Paasche (current-year weighted) index, was the best index number for that and all other purposes, as

it came closer than any other formula to satisfying seven tests for such desirable properties as determinateness, proportionality, and independence of the units of measurement. Later research demonstrated that no formula can satisfy more than six of the seven tests, although, which one should be dropped remains an open question. Three quarters of a century later, the "Fisher ideal index" began to be adopted by governments.

Beyond his work, Fisher encouraged quantitative research by others, notably Yale dissertations by J. Pease Norton [16] and Chester A. Phillips [17], and through his role as founding president of the Econometric Society. Norton's *Statistical Studies of the New York Money Market* is now recognized as a landmark in time-series analysis, while Phillips's *Bank Credit* (together with later work by Fisher's former student James Harvey Rogers) analyzed the creation and absorption of bank deposits by the banking system [4]. Arguing that fluctuations in the purchasing power of money make money and bonds risky assets, contrary to the widespread "money illusion," Fisher and his students advocated common stocks as a long-term investment, with the return on stocks more than compensating for their risk, once risk is calculated in real rather than in nominal terms.

Fisher was swept up in the "New Economy" rhetoric of the 1920s stock boom. He promoted several ventures, of which by far the most successful was his "Index Visible," a precursor of the Rolodex. Fisher sold Index Visible to Rand Kardex for shares and stock options, which he exercised with borrowed money. In mid-1929, Fisher's net worth was 10 million dollars. Had he died then, he would have been remembered like Keynes as a financial success as well as a brilliant theorist; however, a few years later, Fisher's debts exceeded his assets by a million dollars—a loss of 11 million dollars, which, as John Kenneth Galbraith remarked, was "a substantial sum of money, even for a professor of economics" [1, 3]. Worst of all for his public and professional reputation, Fisher memorably asserted in October 1929, on the eve of the Wall Street crash, that stock prices appeared to have reached a permanently high plateau. McGrattan and Prescott [15] hold that Fisher was right to deny that stocks were overvalued in 1929 given the prices/earnings multiples of the time. Whether or not Fisher could reasonably be faulted for not

predicting the subsequent errors of public policy that converted the downturn into the Great Depression, and even though many others were just as mistaken about the future course of stock prices, Fisher's mistaken prediction was particularly pithy, quotable, and memorable, and his reputation suffered as severely as his personal finances. Fisher's 1933 article on "The Debt-Deflation Theory of Great Depressions" [11], linking the fragility of the financial system to the nonneutrality of inside nominal debt whose real value grew as the price level fell, was much later taken up by such economists as Hyman Minsky, James Tobin, Ben Bernanke, and Mervyn King [5, 14], but in the 1930s Fisher had lost his audience. Fisher's 1929 debacle (together with his enthusiastic embrace of causes ranging from a new world map projection, the unhealthiness of smoking, and the usefulness of mathematics in economics, through the League of Nations, universal health insurance, and a low-protein diet to, more regrettably, prohibition and eugenics) long tarnished his public and professional reputation, but he has increasingly come to be recognized as a great figure in the development of theoretical and quantitative economics, including financial economics.

ROBERT W. DIMAND

Modigliani, Franco

An Italian-born economist who fled the fascist regime of Benito Mussolini at the outbreak of WWII, Modigliani pursued the study of economics at the New School of Social Research (renamed New School University) in New York where he received his doctorate in 1944. He taught at several universities but, from 1962 on, he stayed at the Massachusetts Institute of Technology. His famous dissertation on the Keynesian system served as a springboard for many of his lifetime contributions, which include stabilization policies, the FRB–MIT–Penn–SSRC Model (MPS), the Modigliani–Miller (M&M) theorem (**Modigliani–Miller Theorem**) and the life cycle hypothesis (LCH). Modigliani was awarded the Nobel Memorial Prize in economics in 1985 for research in the latter two areas.

Modigliani contributed to making the disciplines of financial economics and macroeconomics operational, and thus more quantitative from a neoclassical perspective. The influence of his teachers, particularly J. Marschak and A. Wald, is seen in his quantitative MPS model based on Keynesian economic thought and his M&M hypothesis in financial economics. The macroeconomic framework that Modigliani built emphasized the savings, consumption, investment, and liquidity components of the Keynesian model. He explained the anomalous fluctuations of the savings (S) to income (Y) ratio during the 1940s and 1950s. He explained the S/Y ratio by the relative position in the income distribution of individuals, and by secular and cyclical changes in income ([3], Vol. 2). The secular changes represent differences in real income per capita above the highest level reached in any preceding year, signifying his contribution to the relative income hypothesis in consumption theory. The cyclical changes represent variation in money income measured by an index, $(Y_t - Y_t^0)/Y_t$, where Y_t is real income per capita in current time, and Y_t^0 is the past peak level of such income. He estimated that the secular and the cyclical affects on income were approximately 0.1% and 0.125%, respectively. These coefficients translate to an S/Y ratio of about 11.7%. Klein and Ozmucur [1] revisited Modigliani's S/Y specification with a much larger sample size and were able to reaffirm the robustness of the model.

In 1954, Modigliani laid the groundwork for the now-famous life cycle hypothesis (LCH) ([5], Vol. 6, pp. 3–45). The LCH bracketed broader macroeconomic problems such as why S/Y is larger in rich countries than in poor countries; why S is greater for farm families than urban families; why lower status urban families save less than other urban families; why when a higher future income is expected, more of current income will be consumed now; why in countries with rising income that is expected to continue to increase, S/Y will be smaller; and why property income that mostly accrues to the rich is largely saved, whereas wages that are mostly earned by the poor are largely spent. To answer these questions, the LCH model maintains the relative income concept of the early S/Y model. The income concept is, however, more encompassing in being high or low relative to the individual's lifetime or permanent income, marking Modigliani's contribution to the permanent income hypothesis in consumption theory. The LCH captures how individuals save when they are young, spend when they are old, and make bequests to their children. In that scenario, consumption, C is uniform over time, T , or $C(T) = (N/L)\bar{Y}$, where L is the number of years the representative individual lives; $N < L$ is the number of years the individual earns labor income, and $\bar{Y}$ is average income. Average income is represented by a flat line, $Y(T)$ up to N , which falls to zero after N , when the individual retires. Since income is earned for N periods, lifetime income is NY , and savings is defined as the excess of $Y(T)$ over $C(T)$.

The empirical estimate of the LCH included a wealth-effect variable on consumption. Saving during an individual's early working life is one way in which wealth accumulates. Such an accumulation of wealth reaches a peak during the person's working age when income is highest. Individuals also inherit wealth. If the initial stock of wealth is A_0 , then, at a certain age, τ , a person's consumption can be expressed as $(L - \tau)C = A + (N - \tau)Y$. Thus, we have a model of consumption explained by income and wealth or assets that can be confronted with data. An early estimate of the coefficient of this LCH model yielded $C = 0.76Y + 0.073A$ (Modigliani, *ibid.*, 70). The result reconciled an early controversy that the short-run propensity to consume from income was between 70% and 80%, and the long-run propensity was approximately 100%. The

reconciliation occurs because the short-run marginal propensity to consume (MPC) is 0.766, and assuming assets, A , is approximately five times income, while labor income is approximately 80% of income, then a long-run MPC is approximately $0.98 = 0.8(.76Y) + 5(.073Y)$.

Modigliani's largest quantitative effort was the MPS model. Working with the board of governors of the Federal Reserve Banks (FRB) and the Social Science Research Council (SSRC), Modigliani built the MIT–Penn–SSRC (MPS) econometric model in the 1960s. The 1968 version, which had 171 endogenous and 119 exogenous variables, predicted poorly in the 1970s and 1980s. In 1996, the FRB/US model replaced the MPS by incorporating rational and vector autoregression types of expectations with a view to improve forecasts. The financial sector was the dominant module in the MPS model. The net worth of consumers took the form of the real value of money and debt. The demand for money depended on the nominal interest rate and the current value of output. Unborrowed reserves influenced the short-term money rate of interest and the nominal money supply, and through the term structure effect, the short-term rate affected the long-term rate and hence savings, which is essential for the expansion of output and employment. Out of this process came the following two fitted demand and supply equations that characterized the financial sector:

$$M_d = -0.0021iY - 0.0043r_sY + 0.542Y + 0.0046NP + 0.833Md_{t-1} \quad (1)$$

$$FR = (0.001 - 0.00204S_2 - 0.00237S_3 - 0.00223S_4)\overline{D}_{t-1} + 0.00122i\overline{D}_{t-1} + 0.00144d\overline{D}_{t-1} + 0.646(1 - \delta)\Delta RU - 0.502\delta\Delta CL + 0.394RD + 0.705FR_{t-1} \quad (2)$$

where M_d is demand for deposits held by the public, Y is gross national product (GNP), r_s is the savings deposit rate, i is the available return on short-term assets, P is expected profits, FR is free reserves, S_i are seasonal adjustments, $\overline{D}$ is the expected value of the stock of member banks deposits, RU is unborrowed reserves, CL is commercial loans, RL

is a reserve release term, and δ is a constant. The equations indicate that the cause and effect between unborrowed reserves to GNP works through lags, causing delay responses to policy measures.

Another of Modigliani's noteworthy contributions to quantitative analysis is the Modigliani and Miller (M&M) theorem [6], which has created a revolution in corporate finance equivalent to the revolution in portfolio theory by H. Markowitz and W. Sharpe. The M&M hypothesis stands on two major propositions, namely that "... market value of any firm is independent of its capital structure and is given by capitalizing its expected return at the rate ρ_k appropriate to its class," and that "*the average cost of capital to any firm is completely independent of the capital structure and is equal to the capitalization rate of a pure equity stream of its class*" (Italics original) ([4], Vol. 3, 10–11). The M&M model can be demonstrated for a firm with no growth, no new net investment, and no taxes. The firm belongs to a risk group in which its shares can be substituted for one another.

The value of the firm can be written as $V_j \equiv S_j + D_j = \overline{X}_j / \rho_j$, where $\overline{X}_j$ measures expected return on assets, ρ_j measures interest rate for a given risk class, D_j is market value of bonds, and S_j is the market value of stocks. For instance, if the earnings before interest and taxes (EBIT) are \$5000 and if the low-risk interest is 10%, then the net operating income is \$50 000.

The proposition of the M&M hypothesis is often expressed as an invariance principle based on the idea that the value of a firm is independent of how it is financed. The proof of this invariance is based on arbitrage. As stated by Modigliani, "... an investor can buy and sell stocks and bonds in such a way as to exchange one income stream for another ... the value of the overpriced shares will fall and that of the under priced shares will rise, thereby tending to eliminate the discrepancy between the market values of the firms" (ibid., p. 11). For example, an investor can get a 6% return either by holding the stocks of an unlevered firm ($0.06X_1$), or holding the stocks and debts of a levered firm, that is, $[0.06(X_2 - rD_2)$ of stocks + $0.06rD_2$ of debts], where the subscripts refer to firms, X is stock, D is debt, and r is return.

The M&M hypothesis was a springboard for many new works in finance. A first extension of the model by the authors reflected the effect of corporate tax effects. Further analysis incorporating the effects of

personal and corporate income taxes does not change the value of the firm because both personal and corporate tax rates tend to cancel out. Researchers dealt with questions that arise when the concept of risk class used in the computation of a firm's value is replaced with perfect market assumptions, and when mean–variance models are used instead of arbitrage. The value of the firm was also found to be independent of dividend policy. By changing the discount rate for the purpose of calculating a firm's present value, it was found that bankruptcy can have an effect on the value of a firm. Macroeconomic variables such as the inflation rate can result in the underestimation of the value of a firm's equity. The M&M theorem has been extended into many areas of modern research. It supports the popular Black–Scholes capital structure model. It has been used to validate the effect of the Tax Reform Act of 1986 on values of the firm. Modern capital asset pricing model (CAPM) scholars such as Sharpe (**Sharpe, William F.**), J. Lintner, and J. Treynor [2] were influenced by the M&M result in the construction of their financial models and ratios.

On a personal level, Modigliani was an outstandingly enthusiastic, passionate, relentless, and focus-driven teacher and exceptional researcher whose arena was both economic theory and the real empirical world.

Arrow, Kenneth

Most financial decisions are made under conditions of uncertainty. Yet a formal analysis of markets under uncertainty emerged only recently, in the 1950s. The matter is complex as it involves explaining how individuals make decisions when facing uncertain situations, the behavior of market instruments such as insurance, securities, and their prices, the welfare properties of the distribution of goods and services under uncertainty, and how risks are shared among the traders. It is not even obvious how to formulate market clearing under conditions of uncertainty. A popular view in the middle of the last century was that markets would only clear on the average and asymptotically in large economies.^a This approach was a reflection of how insurance markets work, and followed a notion of actuarially fair trading.

A different formulation was proposed in the early 1950s by Arrow and Debreu [10, 12, 30]. They introduced an economic theory of markets in which the treatment of uncertainty follows basic principles of physics. The contribution of Arrow and Debreu is as fundamental as it is surprising. For Arrow and Debreu, markets under uncertainty are formally identical to markets without uncertainty. In their approach, uncertainty all but disappears.^b

It may seem curious to explain trade with uncertainty as though uncertainty did not matter. The disappearing act of the issue at stake is an unusual way to think about financial risk, and how we trade when facing such risks. But the insight is valuable. Arrow and Debreu produced a rigorous, consistent, general theory of markets under uncertainty that inherits the most important properties of markets without uncertainty. In doing so, they forced us to clarify what is intrinsically different about uncertainty.

This article summarizes the theory of markets under uncertainty that Arrow and Debreu created, including critical issues that arise from it, and also its legacy. It focuses on the way Arrow introduced securities: how he defined them and the limits of his theory. It mentions the theory of insurance that Arrow pioneered together with Malinvaud and others [6], as well as the theory of risk bearing that Arrow developed on the basis of expected utility [7], following the axioms of Von Neumann

and Morgenstern [41], Harsanyi and Milnor [33], De Groot [31], and Villegas [40]. The legacy of Arrow's work is very extensive and some of it surprising. This article describes his legacy along three lines: (i) individual and idiosyncratic risks, (ii) rare risks and catastrophic events, and (iii) endogenous uncertainty.

Biographical Background

Kenneth Joseph Arrow is American economist and joint winner of the Nobel Memorial Prize in Economics with John Hicks in 1972. Arrow taught at Stanford University and Harvard University. He is one of the founders of modern (post World War II) economic theory, and one of the most important economists of the twentieth century. For a full biographical note, the reader is referred to [18]. Born in 1921 in New York City to Harry and Lilian Arrow, Kenneth was raised in the city. He graduated from Townsend Harris High School and earned a bachelor's degree from the City College of New York studying under Alfred Tarski. After graduating in 1940, he went to Columbia University and after a hiatus caused by World War II, when he served with the Weather Division of the Army Air Forces, he returned to Columbia University to study under the great statistician Harold Hotelling at Columbia University. He received a master's degree in 1941 studying under A. Wald, who was the supervisor of his master's thesis on stochastic processes. From 1946 to 1949 he spent his time partly as a graduate student at Columbia and partly as a research associate at the Cowles Commission for Research in Economics at the University of Chicago; it was in Chicago that he met his wife Selma Schweitzer. During that time, he also held the position of Assistant Professor of Economics at the University of Chicago. Initially interested in following a career as an actuary, in 1951 he earned his doctorate in economics from Columbia University working under the supervision of Harold Hotelling and Albert Hart. His published work on risk started in 1951 [3]. In developing his own approach to risk, Arrow grapples with the ideas of Shackle [39], Knight [35], and Keynes [34] among others, seeking and not always finding a rigorous mathematical foundation. His best-known works on financial markets date back to 1953 [3]. These works provide a solid foundation based on the

role of securities in the allocation of risks [4, 5, 7, 9, 10]. His approach can be described as a state contingent security approach to the allocations of risks in an economy, and is largely an extension of the same approach he followed in his work on general equilibrium theory with Gerard Debreu, for which he was awarded the Nobel Prize in 1972 [8]. Nevertheless, his work connects also with social issues of risk allocation and with the French literature of the time, especially [1, 2].

Markets under Uncertainty

The Arrow–Debreu theory conceptualizes uncertainty with a number of possible states of the world $s = 1, 2, \dots$ that may occur. Commodities can be in one of several states, and are traded separately in each of the states of nature. In this theory, one does not trade a good, but a “contingent good”, namely, a good in each state of the world: apples when it rains and apples when it shines [10, 12, 30]. This way the theory of markets with N goods and S states of nature is formally identical to the theory of markets without uncertainty but with $N \times S$ commodities. Traders trade “state contingent commodities”. This simple formulation allows one to apply the results of the theory of markets without uncertainty, to markets with uncertainty. One recovers most of the important results such as (i) the existence of a market equilibrium and (ii) the “invisible hand theorem” that establishes that market solutions are always Pareto efficient. The approach is elegant, simple, and general.

Along with its elegance and simplicity, the formulation of this theory can be unexpectedly demanding. It requires that we all agree on all the possible states of the world that describe “collective uncertainty”, and that we trade accordingly. This turns out to be more demanding than it seems: for example, one may need to have a separate market for apples when it rains than when it does not, and separate market prices for each case. The assumption requires $N \times S$ markets to guarantee market efficiency, a requirement that in some cases militates against the applicability of the theory. In a later article, Arrow simplified the demands of the theory and reduced the number of markets needed for efficiency by defining “securities”, which are different payments of money exchanged among the traders in different states of

nature [4, 5]. This new approach no longer requires trading “contingent” commodities but rather trading a combination of commodities and securities. Arrow proves that by trading commodities and securities, one can achieve the same results as trading state contingent commodities [4, 5]. Rather than needing $N \times S$ markets, one needs a fewer number of markets, namely, N markets for commodities and $S - 1$ markets for securities. This approach was a great improvement and led to the study of securities in a rigorous and productive manner, an area in which his work has left a large legacy. The mathematical requirement to reach Pareto efficiency was simplified gradually to require that the securities traded should provide for each trader a set of choices with the same dimension as the original state contingent commodity approach. When this condition is not satisfied, the markets are called “incomplete”. This led to a large literature on incomplete markets, for example, [26, 32], in which Pareto efficiency is not assured, and government intervention may be required, an area that exceeds the scope of this article.

Individual Risk and Insurance

The Arrow–Debreu theory is not equally well suited for all types of risks. In some cases, it could require an unrealistically large number of markets to reach efficient allocations. A clear example of this phenomenon arises for those risks that pertain to one individual at a time, called *individual risks*, which are not readily interpreted as states of the world on which we all agree and are willing to trade. Individuals’ accidents, illnesses, deaths, and defaults, are frequent and important risks that fall under this category. Arrow [6] and Malinvaud [37] showed how individual uncertainty can be reformulated or reinterpreted as collective uncertainty. Malinvaud formalized the creation of states of collective risks from individual risks, by lists that describe all individuals in the economy, each in one state of individual risk. The theory of markets can be reinterpreted accordingly [14, 37, 38], yet remains somewhat awkward. The process of trading under individual risk using the Arrow–Debreu theory requires an unrealistically large number of markets. For example with N individuals, each in one of two individual states G (good) and B (bad), the number of (collective) states that are required to apply the Arrow–Debreu

theory is $S = 2^N$. The number of markets required is as above, either $S \times N$ or $N + S - 1$. But with $N = 300$ million people, as in the US economy, applying the Arrow–Debreu approach would require $N \times S = N \times 2^{300 \text{ million}}$ markets to achieve Pareto efficiency, more markets than the total amount of particles in the known universe [25]. For this reason, individual uncertainty is best treated with another formulation of uncertainty involving individual states of uncertainty and insurance rather than securities, in which market clearing is defined on the average and may never actually occur. In this new approach, instead of requiring $N + S - 1$ markets, one requires only N commodity markets and, with two states of individual risk, just one security: an insurance contract suffices to obtain asymptotic efficiency [37, 38]. This is a satisfactory theory of individual risk and insurance, but it leads only to asymptotic market clearing and Pareto efficiency. More recently, the theory was improved and it was shown that one can obtain exact market-clearing solutions and Pareto-efficient allocations based on N commodity markets with the introduction of a limited number of financial instruments called *mutual insurance* [14]. It is shown in [14] that if there are N households (consisting of H types), each facing the possibility of being in S individual states together with T collective states, then ensuring Pareto optimality requires only $H(S - 1)T$ independent mutual insurance policies plus T pure Arrow securities.

Choice and Risk Bearing

Choice under uncertainty explains how individuals rank risky outcomes. In describing how we rank choices under uncertainty, one follows principles that were established to describe the way nature ranks what is most likely to occur, a topic that was widely explored and is at the foundation of statistics [31, 40]. To explain how individuals choose under conditions of uncertainty, Arrow used behavioral axioms that were introduced by Von Neumann and Morgenstern [41] for the theory of games^c and axioms defined by De Groot [31] and Villegas [40] for the foundation of statistics. The main result obtained in the middle of the twentieth century was that under rather simple behavioral assumptions, individuals behave as though they were optimizing

an “expected utility function”. This means that they behave as though they have (i) a utility u for commodities, which is independent of the state of nature, and (ii) subjective probabilities about how likely are the various states of nature. Using the classic axioms one constructs a ranking of choice under uncertainty obtaining a well-known expected utility approach. Specifically, traders choose over “lotteries” that achieve different outcomes in different states of nature. When states of nature and outcomes are represented by real numbers in R , a lottery is a function $f : R \rightarrow R^N$, a utility is a function $u : R^N \rightarrow R$, and a subjective probability is $p : R \rightarrow [0, 1]$ with $\int_R p(s) = 1$. Von Neumann, Arrow, and Hershstein and Milnor, all obtained the same classic “representation theorem” that identifies choice under uncertainty by the ranking of lotteries according to a real-valued function W , where W has the now familiar “expected utility” form:

$$W(f) = \int_{s \in R} p(s) \cdot u(f(s)) \, ds \quad (1)$$

The utility function u is typically bounded to avoid paradoxical behavior. The expected utility approach just described has been generally used since the mid-twentieth century. Despite its elegance and appeal, from the very beginning, expected utility has been unable to explain a host of experimental evidence that was reported in the work of Allais [2] and others. There has been a persistent conflict between theory and observed behavior, but no axiomatic foundation to replace Von Neumann’s foundational approach. The reason for this discrepancy has been identified more recently, and it is attributed to the fact that expected utility is dominated by frequent events and neglects rare events—even those that are potentially catastrophic, such as widespread default in today’s economies. That expected utility neglects rare events was shown in [17, 19, 23]. In [23], the problem was traced back to Arrow’s axiom of monotone continuity [7], which Arrow attributed to Villegas [40], and to the corresponding continuity axioms of Hershstein and Milnor, and De Groot [31], who defined a related continuity condition denoted “ SP_4 ”. Because of this property, on which Arrow’s work is based, the expected utility approach has been characterized as the “dictatorship” of frequent events, since it is dominated by the consideration of “normal” and frequent events [19]. To correct this bias, and to represent more accurately how we choose

under uncertainty, and to arrive at a more realistic meaning of rationality, a new axiom was added in [17, 19, 21], requiring equal treatment for frequent and for rare events. The new axiom was subsequently proven to be the logic negation of Arrow's monotone continuity that was shown to neglect small probability events [23].

The new axioms led to a "representation theorem" according to which the ranking of lotteries is a modified expected utility formula

$$W(f) = \int_{s \in R} p(s) \cdot u(f(s)) ds + \phi(f) \quad (2)$$

where ϕ is a continuous linear function on lotteries defined by a finite additive measure, rather than a countably additive measure [17, 19]. This measure assigns most weight to rare events. The new formulation has both types of measures, so the new characterization of choice under uncertainty incorporates both (i) frequent and (ii) rare events in a balanced manner, conforming more closely to the experimental evidence on how humans choose under uncertainty [15]. The new specification gives well-deserved importance to catastrophic risks, and a special role to fear in decision making [23], leading to a more realistic theory of choice under uncertainty and foundations of statistics, [15, 23, 24]. The legacy of Kenneth Arrow's work is surprising but strong: the new theory of choice under uncertainty coincides with the old when there are no catastrophic risks so that, in reality, the latter is an extension of the former to incorporate rare events. Some of the most interesting applications are to environmental risks such as global warming [25]. Here Kenneth Arrow's work was prescient: Arrow was a contributor to the early literature on environmental risks and irreversibilities [11], along with option values.

Endogenous Uncertainty and Widespread Default

Some of the risks we face are not created by nature. They are our own creation, such as global warming or the financial crisis of 2008 and 2009 anticipated in [27]. In physics, the realization that the observer matters, that the observer is a participant and creates uncertainty, is called *Heisenberger's uncertainty principle*. The equivalent in economics is an uncertainty principle that describes how we create risks

through our economic behavior. This realization led to the new concept of "markets with endogenous uncertainty", created in 1991, and embodied in early articles [16, 27, 28] that established some of the basic principles and welfare theorems in markets with endogenous uncertainty. This, and other later articles ([20, 25, 27, 36]), established basic principles of existence and the properties of the general equilibrium of markets with endogenous uncertainty. It is possible to extend the Arrow–Debreu theory of markets to encompass markets with endogenous uncertainty and also to prove the existence of market equilibrium under these conditions [20]. But in the new formulation, Heisenberg's uncertainty principle rears its quizzical face. It is shown that it is no longer possible to fully hedge the risks that we create ourselves [16], no matter how many financial instruments we create. The equivalent of Russel's paradox in mathematical logic appears also in this context due to the self-referential aspects of endogenous uncertainty [16, 20]. Pareto efficiency of equilibrium can no longer be ensured. Some of the worst economic risks we face are endogenously determined—for example, those that led to the 2008–2009 global financial crisis [27]. In [27] it was shown that the creation of financial instruments to hedge individual risks—such as credit default insurance that is often a subject of discussion in today's financial turmoil—by themselves induce collective risks of widespread default. The widespread default that we experience today was anticipated in [27], in 1991, and in 2006, when it was attributed to endogenous uncertainty created by financial innovation as well as to our choices of regulation or deregulation of financial instruments. Examples are the extent of reserves that are required for investment banking operations, and the creation of mortgage-backed securities that are behind many of the default risks faced today [29]. Financial innovation of this nature, and the attendant regulation of new financial instruments, causes welfare gains for individuals—but at the same time creates new risks for society that bears the collective risks that ensue, as observed in 2008 and 2009. In this context, an extension of the Arrow–Debreu theory of markets can no longer treat markets with endogenous uncertainty as equivalent to markets with standard commodities. The symmetry of markets with and without uncertainty is now broken. We face a brave new world of financial innovation and the

endogenous uncertainty that we create ourselves. Creation and hedging of risks are closely linked, and endogenous uncertainty has acquired a critical role in market performance and economic welfare, an issue that Kenneth Arrow has more recently tackled himself through joint work with Frank Hahn [13].

Acknowledgments

Many thanks are due to Professors Rama Cont and Perry Mehrling of Columbia University and Barnard College, respectively, for their comments and excellent suggestions.

End Notes

^aSee [37, 38]; later on Werner Hildenbrand followed this approach.

^bThey achieved the same for their treatment of economic dynamics. Trading over time and under conditions of uncertainty characterizes financial markets.

^cAnd similar axioms used by Hershman and Milnor [33].

Efficient Markets Theory: Historical Perspectives

Without any doubt, it can be said that efficient market hypothesis (EMH) was crucial in the emergence of financial economics as a proper subfield of economics. But this was not its original goal: EMH was initially created to give a theoretical explanation of the random character of stock market prices.

The historical roots of EMH can be traced back to the nineteenth century and the early twentieth century in the work of Regnault and Bachelier, but their work was isolated and not embedded in a scientific community interested in finance. More immediate roots of the EMH lie in the empirical work of Cowles, Working, and Kendall from 1933 to 1959, which laid the foundation for the key works published in the period from 1959 (Roberts) to 1976 (Fama's reply to LeRoy). More than any other single contributor, it was Fama [7] in his 1965 dissertation, building on the work of Roberts, Cowles, and Cootner, who formulated the EMH, suggesting that stock prices reflect all available information, and that, consequently, the actual value of a security is equal to its price. In addition, because new information arrives randomly, stock prices fluctuate randomly.

The idea that stock prices fluctuate randomly was not new: in 1863, a French broker, Jules Regnault [20], had already suggested it. Regnault was the first author to put forward this hypothesis, to validate it empirically, and to give it a theoretical interpretation. In 1900, Louis Bachelier [1], a French mathematician, used Regnault's hypothesis and framework to develop the first mathematical model of Brownian motion, and tested the model by using it to price futures and options. In retrospect, we can recognize that Bachelier's doctoral dissertation constitutes the first work in mathematical finance. Unfortunately for him, however, financial economics did not then exist as a scientific field, and there was no organized scientific community interested in his research. Consequently, both Regnault and Bachelier were ignored by economists until the 1960s.

Although these early authors did suggest modeling stock prices as a stochastic process, they did not formulate the EMH as it is known today. EMH was genuinely born in linking three elements that originally existed independently of each other: (i) the

mathematical model of a stochastic process (random walk, Brownian motion, or martingale); (ii) the concept of economic equilibrium; and (iii) the statistical results about the unpredictability of stock market prices. EMH's creation took place only between 1959 and 1976, when a large number of economists became familiar with these three features. Between the time of Bachelier and the development of EMH, there were no theoretical preoccupations *per se* about the random character of stock prices, and research was only empirical.

Empirical Research between 1933 and 1959

Between 1933 and the end of the 1950s, only three authors dealt with the random character of stock market prices: Cowles [3, 4], Working [24, 25], and Kendall [13]. They compared stock price fluctuations with random simulations and found similarities. One point must be underlined: these works were strictly statistical, and no theory explained these empirical results.

The situation changed at the end of the 1950s and during the 1960s because of three particular events. First, the Koopmans–Vining controversy at the end of 1940s led to a decline of descriptive approaches and to the increased use of modeling based on theoretical foundations. Second, modern probability theory, and consequently also the theory of stochastic processes, became usable for nonmathematicians. Significantly, economists were attracted to the new formalisms by some features that were already familiar consequences of economic equilibrium. Most important, the zero expected profit when prices follow a Brownian motion reminded economists of the zero marginal profit in the equilibrium of a perfectly competitive market. Third, research on the stock market became more and more popular among scholars: groups of researchers and seminars in financial economics became organized; scientific journals such as the *Journal of Financial and Quantitative Analysis* were created and a community of scholars was born. This context raised awareness about the need for theoretical investigations, and these investigations, in turn, allowed the creation of the EMH.

Theoretical Investigations during the 1960s

Financial economists did not speak immediately of EMH; they talked about “random walk theory”. Following his empirical results, Working [26] was the first author to suggest a theoretical explanation; he established an explicit link between the unpredictable arrival of information and the random character of stock market price changes. However, this paper made no link with economic equilibrium and, probably for this reason, it was not widely diffused. Instead, it was Roberts [21], a professor at the University of Chicago, who first suggested a link between economic concepts and the random walk model by using the “arbitrage proof” argument that had been popularized by Modigliani and Miller [19]. Then, Cowles [5] made an important step by identifying a link between financial econometric results and economic equilibrium. Finally, two years later, Cootner [2] linked the random walk model, information, and economic equilibrium, and exposed the idea of EMH, although he did not use that expression.

Cootner [2] had the essential idea of EMH, but he did not make the crucial empirical link because he considered that real-world stock price variations were not purely random. This point of view was defended by economists from MIT (such as Samuelson) and Stanford University (such as Working). By contrast, economists from the University of Chicago claimed that real stock markets were perfect, and so were more inclined to characterize them as efficient. Thus, it was a scholar from the University of Chicago, Eugene Fama, who formulated the EMH.

In his 1965 PhD thesis, Fama gave the first theoretical account of EMH. In that account, the key assumption is the existence of “sophisticated traders” who, due to their skills, make a better estimate of intrinsic valuation than do other agents by using all available information. Provided that such traders have predominant access to financial resources, their activity of buying underpriced assets and selling overpriced assets will tend to make prices equal the intrinsic values about which they have a shared assessment and also to eliminate any expectation of profit from trading. Linking these consequences with the random walk model, Fama added that because information arrives randomly, stock prices have to fluctuate randomly. Fama thus offered the first clear

link between empirical results about stock price variations, the random walk model, and economic equilibrium. EMH was born.

Evolution of Fama’s Definition during the 1970s

Five years after his PhD dissertation, Fama [8] offered a mathematical demonstration of the EMH. He simplified his first definition by making the implicit assumption of a representative agent. He also used another stochastic process: the martingale model, which had been introduced to model the random character of stock market prices by Samuelson [22] and Mandelbrot [17]. The martingale model is less restrictive than the random walk model: the martingale model requires only independence of the conditional expectation of price changes, whereas the random walk model requires also independence involving the higher conditional moments (i.e., variance, skewness, and kurtosis) of the probability distribution of price changes. For Fama’s [8] purposes, the most important attraction of the martingale formalism was its explicit reference to a set of information, Φ_t ,

$$E(P_{t+1}|\Phi_t) - P_t = 0 \quad (1)$$

As such, the martingale model could be used to test the implication of EMH that, if all available information is used, the expected profit is null. This idea led to the definition of an efficient market that is generally used nowadays: “a market in which prices always ‘fully reflect’ available information is called ‘efficient’” [8].

However, in 1976, LeRoy [15] showed that Fama’s demonstration is tautological and that his theory is not testable. Fama answered by modifying his definition and he also admitted that any test of the EMH is a test of both market efficiency and the model of equilibrium used by investors. In addition, it is striking to note that the test suggested by Fama [9] (i.e., markets are efficient if stock prices are equal to the prediction provided by the model of equilibrium used) does not imply any clear causality between the random character of stock market prices and the EMH; it is mostly a plausible correlation valid only for some cases.

The Proliferation of Definitions since the 1970s

Fama's modification of his definition proved to be a fateful admission. In retrospect, it is clear that the theoretical content of EMH comprised its suggestion of a link between some mathematical model, some empirical results, and some concept of economic equilibrium. The precise linkage proposed by Fama was, however, only one of many possible linkages, as subsequent literature would demonstrate. Just so, LeRoy [14] and Lucas [16] provided theoretical proofs that efficient markets and the martingale hypothesis are two distinct ideas: martingale is neither necessary nor sufficient for an efficient market. In a similar way, Samuelson [23], who gave a mathematical proof that prices may be permanently equal to the intrinsic value and fluctuate randomly, explained that it cannot be excluded that some agents make profits, contrary to the original definition of EMH. De Meyer and Saley [6] show that stock market prices follow a martingale even if all available information is not contained in stock market prices.

This proliferation at the level of theory has been matched by proliferation at the level of empirical testing, as the definition of EMH has changed depending on the emphasis placed by each author on one particular feature. For instance, Fama *et al.* [10] defined an efficient market as "a market that adjusts rapidly to new information"; Jensen [12] considered that "a market is efficient with respect to information set θ_t if it is impossible to make economic profit by trading on the basis of information set θ_t "; according to Malkiel [18] "the market is said to be efficient with respect to some information set [...] if security prices would be unaffected by revealing that information to all participants. Moreover, efficiency with respect to an information set [...] implies that it is impossible to make economic profits by trading on the basis of [that information set]".

The situation is similar regarding the tests: the type of test used depends on the definition used by the authors and on the data used (for instance, most of the tests are done with low frequency or daily data, while statistical arbitrage opportunities are discernible and exploitable at high frequency using algorithmic trading). Moreover, some authors have used the weakness of the definitions to criticize the very relevance of efficient markets. For instance, Grossman and Stiglitz [11] argued that because information

is costly, prices cannot perfectly reflect all available information. Consequently, they considered that perfectly information-efficient markets are impossible.

The history of EMH shows that the definition of this theory is plural, and the initial project of EMH (the creation of a link between a mathematical model, the concept of economic equilibrium, and statistical results about the unpredictability of stock market prices) has not been fully achieved. Moreover, this theory is not empirically refutable (since a test of the random character of stock prices does not imply a test on efficiency). Nevertheless, financial economists have considered EMH as one of the pillars of financial economics because it played a key role in the creation and history of financial economics by linking financial results with standard economics. This link is the main contribution of EMH.

Econophysics

The Prehistoric Times of Econophysics

The term *econophysics* was introduced in the 1990s, endorsed in 1999 by the publication of Mantegna & Stanley's "An Introduction to Econophysics" [33]. The word "econophysics", paralleling the quests of biophysics or geophysics, suggests that there is a physics-based approach to economics.

From classical to neoclassical economics and until now, economists have been inspired by the conceptual and mathematical developments of the physical sciences and by their remarkable successes in describing and predicting natural phenomena. Reciprocally, physics has been enriched several times by developments first observed in economics. Well before the christening of econophysics as the incarnation of the multidisciplinary study of complex large-scale financial and economic systems, a multitude of small and large collisions have punctuated the development of these two fields. We now mention a few that illustrate the remarkable commonalities and interfertilization.

In his "Inquiry into the Nature and Causes of the Wealth of Nations" (1776), Adam Smith found inspiration in the *Philosophiae Naturalis Principia Mathematica* (1687) of Isaac Newton, specifically based on the (novel at the time) notion of causative forces.

The recognition of the importance of feedbacks to fathom the sheer complexity of economic systems has been at the root of economic thinking for a long time. Toward the end of the nineteenth century, the microeconomists Francis Edgeworth and Alfred Marshall drew on some of the ideas of physicists to develop the notion that the economy achieves an equilibrium state like that described for gases by Clerk Maxwell and Ludwig Boltzmann. The general equilibrium theory now at the core of much of economic thinking is nothing but a formalization of the idea that "everything in the economy affects everything else" [18], reminiscent of mean-field theory or self-consistent effective medium methods in physics, but emphasizing and transcending these ideas much beyond their initial sense in physics.

While developing the field of microeconomics in his "Cours d'Economie Politique" (1897), the economist and philosopher Vilfredo Pareto was

the first to describe, for the distribution of incomes, the eponym power laws that would later become the center of attention of physicists and other scientists observing this remarkable and universal statistical signature in the distribution of event sizes (earthquakes, avalanches, landslides, storms, forest fires, solar flares, commercial sales, war sizes, and so on) punctuating so many natural and social systems [3, 29, 35, 41].

While attempting to model the erratic motion of bonds and stock options in the Paris *Bourse* in 1900, mathematician Louis Bachelier developed the mathematical theory of diffusion (and the first elements of financial option pricing) and solved the parabolic diffusion equation five years before Albert Einstein [10] established the theory of Brownian motion based on the same diffusion equation (also underpinning the theory of random walks) in 1905. The ensuing modern theory of random walks now constitutes one of the fundamental pillars of theoretical physics and economics and finance models.

In the early 1960s, mathematician Benoit Mandelbrot [28] pioneered the use in financial economics of heavy-tailed distributions (Lévy stable laws) as opposed to the traditional Gaussian (normal) law. A cohort of economists, notably at the University of Chicago (Merton Miller, Eugene Fama, and Richard Roll), at MIT (Paul Samuelson), and at Carnegie Mellon University (Thomas Sargent), initially followed his steps. In his PhD thesis, Eugene Fama confirmed that the frequency distribution of the changes in the logarithms of prices was "leptokurtic", that is, with a high peak and fat tails. However, other notable economists (Paul Cootner and Clive Granger) opposed Mandelbrot's proposal, on the basis of the argument that "the statistical theory that exists for the normal case is nonexistent for the other members of the class of Lévy laws." The *coup de grace* was the mounting empirical evidence that the distributions of returns were becoming closer to the Gaussian law at timescales larger than one month, at odds with the self-similarity hypothesis associated with the Lévy laws [7, 23]. Much of the efforts in the econophysics literature of the late 1990s and early 2000s revisited and refined this hypothesis, confirming on one hand the existence of the variance (which rules out the class of Lévy distributions proposed by Mandelbrot), but also suggesting a power-law tail with an exponent close to 3 [16, 32]—several other groups have discussed alternatives, such as exponential [39]

or stretched exponential distributions [19, 24, 26]. Financial engineers actually care about these apparent technicalities because the tail structure controls the Value at Risk and other measures of large losses, and physicists care because the tail may constrain the underlying mechanism(s). For instance, Gabaix *et al.* [14] attribute the large movements in stock market activity to the interplay between the power-law distribution of the sizes of large financial institutions and the optimal trading of such large institutions. In this domain, econophysics focuses on models that can reproduce and explain the main stylized facts of financial time series: non-Gaussian fat tail distribution of returns, long-range autocorrelation of volatility and the absence of correlation of returns, multifractal property of the absolute value of returns, and so on.

In the late 1960s, Benoit Mandelbrot left financial economics but, inspired by this first episode, went on to explore other uncharted territories to show how nondifferentiable geometries (that he coined *fractal*), previously developed by mathematicians from the 1870s to the 1940s, could provide new ways to deal with the real complexity of the world [29]. He later returned to finance in the late 1990s in the midst of the econophysics' enthusiasm to model the multifractal properties associated with the long-memory properties observed in financial asset returns [2, 30, 31, 34, 43].

Notable Contributions

The modern econophysicists are implicitly and sometimes explicitly driven by the hope that the concept of "universality" holds in economics and finance. The value of this strategy remains to be validated [42], as most econophysicists have not yet digested the subtleties of economic thinking and failed to marry their ideas and techniques with mainstream economics. The following is a partial list of a few notable exceptions: precursory physics approach to social systems [15], agent-based models, induction, evolutionary models [1, 9, 11, 21], option theory for incomplete markets [4, 6], interest rate curves [5, 38], minority games [8], theory of Zipf law and its economic consequences [12, 13, 27], theory of large price fluctuations [14], theory of bubbles and crashes [17, 22, 40], random matrix theory applied

to covariance of returns [20, 36, 37], and methods and models of dependence between financial assets [25, 43].

At present, the most exciting progresses seem to be unraveling at the boundary between economics and the biological, cognitive, and behavioral sciences. While it is difficult to argue for a physics-based foundation of economics and finance, physics has still a role to play as a unifying framework full of concepts and tools to deal with the complex. The modeling skills of physicists explain their impressive number in investment and financial institutions, where their data-driven approach coupled with a pragmatic sense of theorizing has made them a most valuable commodity on Wall Street.

Acknowledgments

We would like to thank Y. Malevergne for many discussions and a long-term enjoyable and fruitful collaboration.

GILLES DANIEL & DIDIER SORNETTE

Kolmogorov, Andrei Nikolaevich

Andrei Nikolaevich Kolmogorov was born on April 25, 1903 and died on October 20, 1987 in the Soviet Union.

Springer Verlag published (in German) Kolmogorov's monograph "Foundations of the Theory of Probability" more than seventy-five years ago [3]. In this small, 80-page book, he not only provided the logical foundation of the mathematical theory of probability (axiomatics) but also defined new concepts: conditional probability as a random variable, conditional expectations, notion of independency, the use of Borel fields of probability, and so on. The "Main theorem" in Chapter III "Probability in Infinite Spaces" indicated how to construct stochastic processes starting from their finite-dimensional distributions. His approach has made the development of modern mathematical finance possible.

Before writing "Foundations of the Theory of Probability", Kolmogorov wrote his great paper "Analytical Methods in Probability Theory" [2], which gave birth to the theory of Markov processes in continuous time. In this paper, Kolmogorov presented his famous *forward and backward* differential equations, which are the often-used tools in probability theory and its applications. He also gave credit to L. Bachelier for the latter's pioneering investigations of probabilistic schemes evolving continuously in time.

The two works mentioned earlier laid the groundwork for all subsequent developments of the theory of probability and stochastic processes. Today, it is impossible to imagine the state of these sciences without Kolmogorov's contributions.

Kolmogorov developed many fundamentally important concepts that have determined the progress in different branches of mathematics and other branches of science and arts. Being an outstanding mathematician and scientist, he obtained, besides fundamental results in the theory of probability

[5], the theory of trigonometric series, measure and set theory, the theory of integration, approximation theory, constructive logic, topology, the theory of superposition of functions and Hilbert's thirteenth problem, classical mechanics, ergodic theory, the theory of turbulence, diffusion and models of population dynamics, mathematical statistics, the theory of algorithms, information theory, the theory of automata and applications of mathematical methods in humanitarian sciences (including work in the theory of poetry, the statistics of text, and history), and the history and methodology of mathematics for school children and teachers of school mathematics [4–6]. For more descriptions of Kolmogorov's works, see [1, 7].

ALBERT N. SHIRYAEV

Bernoulli, Jacob

Jacob Bernoulli (1654–1705), the son and grandson of spice merchants in the city of Basel, Switzerland, was trained to be a protestant clergyman, but, following his own interests and talents, instead became the professor of mathematics at the University of Basel from 1687 until his death. He taught mathematics to his nephew Nicolaus Bernoulli (1687–1759) and to his younger brother Johann (John, Jean) Bernoulli (1667–1748), who was trained in medicine, but took over as professor of mathematics at Basel after Jacob's death in 1705. As a professor of mathematics, Johann Bernoulli, in turn, taught mathematics to his sons, including Daniel Bernoulli (1700–1782), known for the St. Petersburg paradox in probability, as well as for work in hydrodynamics. Jacob and Johann Bernoulli were among the first to read and understand Gottfried Wilhelm Leibniz's articles in the *Acta Eruditorum* of 1684 and 1686, in which Leibniz put forth the new algorithm of calculus. They helped to develop and spread Leibniz's calculus throughout Europe, Johann teaching calculus to the Marquis de Hôpital, who published the first calculus textbook. Nicolas Bernoulli wrote his master's thesis [1] on the basis of the manuscripts of Jacob's still unpublished *Art of Conjecturing*, and helped to spread its contents in the years between Jacob's death and the posthumous publication of Jacob's work in 1713 [2]. In the remainder of this article, the name "Bernoulli" without any first name refers to Jacob Bernoulli. (Readers should be aware that many Bernoulli mathematicians are not infrequently confused with each other. For instance, it was Jacob's *son* Nicolaus, also born in 1687, but a painter and not a mathematician, who had the Latin manuscript of [2] printed, and not his *nephew* Nicolaus, although the latter wrote a brief preface.)

As far as the application of the art of conjecturing to economics (or finance) is concerned, much of the mathematics that Jacob Bernoulli inherited relied more on law and other institutional factors than it relied on statistics or mathematical probability, a discipline that did not then exist. Muslim traders had played a significant role in Mediterranean commerce in the medieval period and in the development of mathematics, particularly algebra, as well. Muslim mathematical methods were famously transmitted to

Europe by Leonardo of Pisa, also known as *Fibonacci* [6]. Rather than relying on investments with guaranteed rates of return, which were frowned upon as involving usury, Muslim trade was often carried out by partnerships or companies, many involving members of extended families. Such partnerships would be based on a written contract between those involved, spelling out the agreed-upon division of the profits once voyagers had returned and the goods had been sold, the shares of each partner depending upon their investment of cash, supply of capital goods such as ships or warehouses, and labor. According to the Islamic law, if one of the partners in such an enterprise died before the end of the anticipated period of the venture, his heirs were entitled to demand the dissolution of the firm, so that they might receive their legal inheritances. Not infrequently, applied mathematicians were called upon to calculate the value of the partnership on a given intermediate date, so that the partnership could be dissolved fairly.

In Arabic and then Latin books of commercial arithmetic or business mathematics in general (geometry, for instance, volumes of barrels, might also be included), there were frequently problems of "societies" or partnerships, which later evolved into the so-called "problem of points" concerning the division of the stakes of a gambling game if it were terminated before its intended end. Typically, the values of the various partners' shares were calculated using (i) the amounts invested; (ii) the length of time it was invested in the company if all the partners were not equal in this regard; and (iii) the original contract, which generally specified the division of the capital and profits among partners traveling to carry out the business and those remaining at home. The actual mathematics involved in making these calculations was similar to the mathematics of calculating the price of a mixture [2, 7, 8]. (If, as was often the case, "story problems" were described only in long paragraphs, what was intended might seem much more complex than if everything could have been set out in the subsequently developed notation of algebraic equations.)

In Part IV of [2], Bernoulli had intended to apply the mathematics of games of chance, expounded in Parts I–III of the book on the basis of Huygens' work, by analogy, to civil, moral, and economic problems. The fundamental principle of Huygens' and Bernoulli's mathematics of games of chance was that the game should be fair and that players should

pay to play a game in proportion to their expected winnings. Most games, like business partnerships, were assumed to involve only the players, so that the total paid in would equal the total paid out at the end. Here, a key concept was the number of “cases” or possible alternative outcomes. If a player might win a set amount if a die came up a 1, then there were said to be six cases, corresponding to the six faces of the die, of which one, the 1, would be favorable to that player. For this game to be fair, the player should pay in one-sixth of the amount he or she would win if the 1 were thrown.

Bernoulli applied this kind of mathematics in an effort to quantify the evidence that an accused person had committed a crime by systematically combining all the various types of circumstantial evidence of the crime. He supposed that something similar might be done to judge life expectancies, except that no one knew all the “cases” that might affect life expectancy, such as the person’s inherited vigor and healthiness, the diseases to which a person might succumb, the accidents that might happen, and so forth. With the law that later came to be known as the *weak law of large numbers*, Bernoulli proposed to discover *a posteriori* from the results many times observed in similar situations what the ratios of unobserved underlying “cases” might be. Most people realize, Bernoulli said, that if you want to judge what may happen in the future by what has happened in the past, you are less liable to be mistaken if you have made more observations or have a longer time series of outcomes. What people do not know, he said, is whether, if you make more and more observations, you can be more and more sure, without limit, that your prediction is reliable. By his proof he claimed to show that there was no limit to the degree of confidence or probability one might have that the ratio of results would fall within some interval around an expected ratio. In addition, he made a rough calculation of the number of trials (later called *Bernoulli trials*) that would be needed for a proposed degree of certainty. The mathematics he used in his proof basically involved binomial expansions and the possible combinations and permutations of outcomes (“successes” or “failures”) over a long series of trials. After a long series of trials, the distribution of ratios of outcomes would take the shape of a bell curve, with increasing percentages of outcomes clustering around the central value. For a comparison of Jacob

Bernoulli’s proof with Nicolaus Bernoulli’s proof of the same theorem, see [5].

In correspondence with Leibniz, Bernoulli unsuccessfully tried to obtain from Leibniz a copy of Jan De Witt’s rare pamphlet, in Dutch, on the mathematics of annuities—this was the sort of problem to which he hoped to apply his new mathematical theory [4]. Leibniz, in reply, without having been told the mathematical basis of Bernoulli’s proof of his law for finding, *a posteriori*, ratios of cases, for instance, of surviving past a given age, objected that no such approach would work because the causes of death might be changeable over time. What if a new disease should make an appearance, leading to an increase of early deaths? Bernoulli’s reply was that, if there were such changed circumstances, then it would be necessary to make new observations to calculate new ratios for life expectancies or values of annuities [2].

But what if not only were there no fixed ratios of cases over time, but no such regularities (underlying ratios of cases) at all? For Bernoulli this was not a serious issue because he was a determinist, believing that from the point of view of the Creator everything is determined and known eternally. It is only because we humans do not have such godlike knowledge that we cannot know the future in detail. Nevertheless, we can increase the security and prudence of our actions through the application of the mathematical art of conjecturing that he proposed to develop. Even before the publication of *The Art of Conjecturing*, Abraham De Moivre had begun to carry out with great success the program that Bernoulli had begun [3]. Although, for Bernoulli, probability was an epistemic concept, and expectation was more fundamental than relative chances, De Moivre established mathematical probability on the basis of relative frequencies.

EDITH DUDLEY SYLLA

Treynor, Lawrence Jack

Jack Lawrence Treynor was born in Council Bluffs, Iowa, on February 21, 1930 to Jack Vernon Treynor and Alice Cavin Treynor. In 1951, he graduated from Haverford College on Philadelphia's Main Line with a Bachelors of Arts degree in mathematics. He served two years in the US Army before moving to Cambridge, MA to attend Harvard Business School. After a year writing cases for Professor Robert Anthony, Treynor went to work for the Operations Research department at Arthur D. Little in 1956.

Treynor was particularly inspired by the 1958 paper coauthored by Franco Modigliani and Merton H. Miller, titled "The Cost of Capital, Corporation Finance, and the Theory of Investment." At the invitation of Modigliani, Treynor spent a sabbatical year at MIT between 1962 and 1963. While at MIT, Treynor made two presentations to the finance faculty, the first of which, "Toward a Theory of the Market Value of Risky Assets," introduced the capital asset pricing model (CAPM). The CAPM says that the return on an asset should equal the rate on a risk-free rate plus a premium proportional to its contribution to the risk in the market portfolio. The model is often referred to as the *Treynor–Sharpe–Lintner–Mossin CAPM* to reflect the fact that it was simultaneously and independently developed by multiple individuals, albeit with slight differences. Although Treynor's paper was not published until Robert Korajczyk included the unrevised version in his 1999 book, *Asset Pricing and Portfolio Performance*, it is also included in the "Risk" section of Treynor's own 2007 book, *Treynor on Institutional Investing* (Wiley, 2008). William F. Sharpe's 1964 version, which was built on the earlier work of Harry M. Markowitz, won the Nobel Prize for Economics in 1990.

The CAPM makes no assumptions about the factor structure of the market. In particular, it does not assume the single-factor structure of the so-called market model. However, in his *Harvard Business Review* papers on performance measurement, Treynor assumed a single factor. He used a regression of returns on managed funds against returns on the "market" to estimate the sensitivity of the fund to the market factor and then used the slope of that regression line to estimate the contribution of market fluctuations to a fund's rate of return, which

permitted him to isolate the portion of fund return that was actually due to the selection skills of the fund manager. In 1981, Fischer Black wrote an open letter in the *Financial Analysts Journal*, stating that Treynor had "developed the capital asset pricing model before anyone else."

In his second *Harvard Business Review* paper, Treynor and Kay Mazuy used a curvilinear regression line to test whether funds were more sensitive to the market in the years when the market went up *versus* the years when the market went down.

When Fischer Black arrived at Arthur D. Little in 1965, Black took an interest in Treynor's work and later inherited Treynor's caseload (after Treynor went to work for Merrill Lynch.) In their paper, "How to Use Security Analysis to Improve Portfolio Selection," Treynor and Black proposed viewing portfolios as having three distinct parts: a riskless part, a highly diversified part (devoid of specific risk), and an active part (which would have both specific risk and market risk). The paper spells out the optimal balance, not only between the three parts but also between the individual securities in the active part.

In 1966, Treynor was hired by Merrill Lynch where he headed Wall Street's first quantitative research group. Treynor left Merrill Lynch in 1969 to serve as the editor of the *Financial Analysts Journal*, with which he stayed until 1981. Treynor then joined Harold Arbit in starting Treynor–Arbit Associates, an investment firm based in Chicago. Treynor continues to serve on the advisory boards of the *Financial Analysts Journal* and the *Journal of Investment Management*, where he is also case editor.

In addition to his 1976 book published with William Priest and Patrick Regan titled *The Financial Reality of Pension Funding under ERISA*, Treynor coauthored *Machine Tool Leasing* in 1956 with Richard Vancil of Harvard Business School. Treynor has authored and co-authored more than 90 papers on such topics as risk, performance measurement, economics, trading (market microstructure), accounting, investment value, active management, and pensions. He has also written 20 cases, many published in the *Journal of Investment Management*.

Treynor's work has appeared in the *Financial Analysts Journal*, the *Journal of Business*, the *Harvard Business Review*, the *Journal of Finance*, and the *Journal of Investment Management*, among others. Some of Treynor's works were published under the pen-name "Walter Bagehot," a cover that offered him

anonymity while allowing him to share his often unorthodox theories. He promoted notions such as random walks, efficient markets, risk/return trade-off, and betas that others in the field actively avoided. Treynor has since become renowned not only for pushing the envelope with new ideas but also for encouraging others to do the same as well. Eighteen of his papers have appeared in anthologies.

Two papers that have not been anthologized are “Treynor’s Theory of Inflation” and “Will the Phillips Curve Cause World War III?” In these papers, he points out that, because in industry labor and capital are complements (rather than substitutes, as depicted in economics textbooks), over the business cycle they will become more or less scarce together. However, when capital gets more or less scarce, the identity of the marginal machine will change. If the real wage is determined by the marginal productivity of labor then (as Treynor argues) it is determined by the labor productivity of the marginal machine. As demand rises and the marginal machines get older and less efficient, the real wage falls, but labor negotiations fix the money wage. In order to satisfy the identity

$$\text{money prices} \equiv \frac{\text{money wage}}{\text{real wage}} \quad (1)$$

when the real wage falls, money prices must rise. According to Nobel Laureate Merton Miller, Treynor’s main competitor on the topic, the Phillips curve is “just an empirical regularity” (i.e., just data snooping).

Treynor has won the *Financial Analysts Journal*’s Graham and Dodd Scroll award in 1968, 1982, twice in 1987, for “The Economics of the Dealer Function” and “Market Efficiency and the Bean Jar Experiment,” in 1998 for “Bulls Bears and Market Bubbles”, and in 1999 for “The Investment Value of Brand Franchise.” In 1981 Treynor was again recognized for his research, winning the Graham and Dodd award for “Best Paper” titled “What Does It Take to Win the Trading Game?” In 1987, he was presented with the James R. Vertin Award of the Research Foundation of the Institute of Chartered Financial Analysts, “in recognition of his research, notable for its relevance and enduring value to investment professionals.” In addition, the Financial Analysts Association presented him with the Nicholas Molodovsky Award in 1985, “in recognition of his outstanding contributions to the profession of financial analysis of such significance

as to change the direction of the profession and raise it to higher standards of accomplishment.” He received the Roger F. Murray prize in 1994 from the Institute of Quantitative Research in Finance for “Active Management as an Adversary Game.” That same year he was also named a Distinguished Fellow of the Institute for Quantitative Research in Finance along with William Sharpe, Merton Miller, and Harry Markowitz. In 1997, he received the EBRI Lillywhite Award, which is “awarded to persons who have had distinguished careers in the investment management and employee benefits fields and whose outstanding service enhances Americans’ economic security.” In 2007, he was presented with The Award for Professional Excellence, presented periodically by the CFA Institute Board to “a member of the investment profession whose exemplary achievement, excellence of practice, and true leadership have inspired and reflected honor upon our profession to the highest degree” (Previous winners were Jack Bogle and Warren Buffett.). In 2008, he was recognized as the 2007 IAFE/SunGard Financial Engineer of the Year for his contributions to financial theory and practice.

Treynor taught investments at Columbia University while working at the *Financial Analysts Journal*. Between 1985 and 1988, Treynor taught investments at the University of Southern California.

He is currently President of Treynor Capital Management in Palos Verdes, California.

Rubinstein, Edward Mark

Mark Rubinstein, the only child of Sam and Gladys Rubinstein of Seattle, Washington, was born on June 8, 1944. He attended the Lakeside School in Seattle and graduated in 1962 as one of the two graduation speakers. He earned an A.B. in Economics, magna cum laude, from Harvard College in 1966 and an MBA with a concentration in finance from the Graduate School of Business at Stanford University in 1968. In 1971, Rubinstein earned his PhD. in Finance from the University of California, Los Angeles (UCLA). During this time at UCLA, he was heavily influenced by the microeconomist Jack Hirshleifer. In July 1972, he became an assistant professor in finance at the University of Californian at Berkeley, where he remained for his entire career. He was advanced to tenure unusually early in 1976 and became a full professor in 1980.

Rubinstein's early work concentrated on asset pricing. Specifically, between 1971 and 1973, his research centered on the mean–variance capital asset pricing model and came to include skewness as a measure of risk [3–5]. Rubinstein's extension has new relevance as several researchers have since determined its predictive power in explaining realized security returns. In 1974, Rubinstein's research turned to more general models of asset pricing. He developed an extensive example of multiperiod security market equilibrium, which later became the dominant model used by academics in their theoretical papers on asset pricing. Unlike earlier work, he left the intertemporal process of security returns to be determined in equilibrium rather than as datum (although as special cases he assumed a random walk and constant interest rates). Rubinstein was thus able to derive conditions for the existence of a random walk and an unbiased term structure of interest rates. He also was the first to derive a simple equation in equilibrium for valuing a risky stream of income received over time. He published the first paper to show explicitly how and why in equilibrium investors would want to hold long-term bonds in their portfolios, and in particular would want to hold a riskless (in terms of income) annuity maturing at their death, foreshadowing several strands of later research.

In 1975, Rubinstein began developing theoretical models of “efficient markets.” In 1976, he published a paper showing that the same formula derived by Black and Scholes for valuing options could come from an alternative set of assumptions based on risk aversion and discrete-time trading opportunities. (Black and Scholes had required continuous trading and continuous price movements.)

Working together with Cox *et al.* [1], Rubinstein published the popular and original paper developing the binomial option pricing model, one of the most widely cited papers in financial economics and now probably the most widely used model by professional traders to value derivatives. The model is often referred to as the *Cox–Ross–Rubinstein option pricing (CRR)* model. At the same time, Rubinstein began work with Cox [2] on their own text, *Options Markets*, which was eventually published in 1985 and won the biennial award of the University of Chicago for the best work by professors of business concerning any area of business.

He supplemented his academic work with firsthand experience as a market maker in options when he became a member of the Pacific Stock Exchange. In 1981, together with Hayne E. Leland and John W. O'Brien, Rubinstein founded the Leland O'Brien Rubinstein (LOR) Associates, the original portfolio insurance firm. At the time, the novel idea of portfolio insurance had been put forth by Leland, later fully developed together with Rubinstein, and successfully marketed among large institutional investors by O'Brien. Their business grew extremely rapidly, only to be cut short when they had to share the blame for the October 1987 stock market crash. Not admitting defeat, LOR invented another product that became the first exchange-traded fund (ETF), the SuperTrust, listed on the American Stock Exchange in 1992. Rubinstein also published a related article examining alternative basket vehicles.

In the early 1990s, Rubinstein published a series of eight articles in the *Risk Magazine* showing how option pricing tools could easily be applied to value a host of so-called exotic derivatives, which were just becoming popular.

Motivated by the failure after 1987 of index options to be priced anywhere close to the predictions of the Black–Scholes formula, in an article

published in the *Journal of Finance* [8], he developed an important generalization of the original binomial model, which he called *implied binomial trees*. The article included new techniques for inferring risk-neutral probability distributions from options on the same underlying asset. Rubinstein's revisions of the model provide the natural generalization of the standard binomial model to accommodate arbitrary expiration date risk-neutral probability distributions. This paper, in turn, spurred new academic work on option pricing in the latter half of the 1990s and found immediate application among various professionals. In 1998 and 1999, Rubinstein rounded out his work on derivatives by publishing a second text titled "Rubinstein on Derivatives," which expanded its domain from calls and puts to futures and more general types of derivatives. The book also pioneered new ways to integrate computers as an aid to learning.

After a 1999 debate about the empirical rationality of financial markets with the key behavioral finance theorist, Richard Thaler, Rubinstein began to rethink the concept of efficient markets. In 2001, he published a version of his conference argument in the *Financial Analysts Journal* [6, 7], titled "Rational Markets? Yes or No: The Affirmative Case," which won the Graham and Dodd Plaque award in 2002.

He then returned to the more general theory of investments with which he had begun his research career as a doctoral student. In 2006, Rubinstein [11] published "A History of the Theory of Investments: My Annotated Bibliography"—an academic history of the theory of investments from the thirteenth to the beginning of the twenty-first century, systematizing the knowledge, and identifying the relations between apparently disparate lines of research. No other book has so far been written that comes close to examining in detail the intellectual path that has led to modern financial economics (particularly, in the subarea of investments). Rubinstein shows that the discovery of key ideas in finance is much more complex and multistaged than anyone had realized. Too few are given too much credit, and sometimes original work has been forgotten.

Rubinstein has taught and lectured widely. During his career, he has given 303 invited lectures, including conference presentations, full course seminars, and honorary addresses all over the United

States and around the world. He has served as chairman of the Berkeley finance group, and as director of the Berkeley Program in Finance; he is the founder of the Berkeley Options Database (the first large transaction-level database ever assembled with respect to options and stocks). He has served on the editorial boards of numerous finance journals. He has authored 62 journal articles, published 3 books, and developed several computer programs dealing with derivatives.

Rubinstein is currently a professor of finance at the Haas School of Business at the University of California, Berkeley. Many of his papers are frequently reprinted in survey publications, and he has won numerous prizes and awards for his research and writing on financial economics. He was named "Businessman of the Year" (one of 12) in 1987 by *Fortune* magazine. In 1995, the International Association of Financial Engineers (IAFE) named him the 1995 IAFE/SunGard Financial Engineer of the Year. In 2000, he was elected to Derivatives Strategy Magazine's "Derivatives Hall of Fame" and named in the "RISK Hall of Fame" by *Risk Magazine* in 2002. Of all his awards, the one he cherishes the most is the 2003 Earl F. Cheit Teaching award in the Masters of Financial Engineering Program at the University of California, Berkeley [10] (Rubinstein, M.E. (2003). *A Short Career Biography*. Unpublished.)

Rubinstein has two grown-up children, Maisie and Judd. He lives with Diane Rubinstein in the San Francisco Bay Area.

Infinite Divisibility

We say that a random variable X has an infinitely divisible (ID) *distribution* (in short X is ID) if for all the integers $n \geq 1$ there exist n independent identically distributed (i.i.d) random variables $X_1, \dots, X_n$, such that $X_1 + \dots + X_n \stackrel{d}{=} X$, where $\stackrel{d}{=}$ is equality in distribution. Alternatively, X (or its distribution μ) is ID if for all $n \geq 1$, μ is the n th convolution $\mu_n * \dots * \mu_n$, where μ_n is a probability distribution.

There are several advantages in using infinitely divisible distributions and processes in financial modeling. First, they offer wide possibilities for modeling alternatives to the Gaussian and stable distributions, while maintaining a link with the central limit theorem and a rich probabilistic structure. Second, they are closely linked to Lévy processes: for each ID distribution μ there is a Lévy process (see **Lévy Processes**) $\{X_t : t \geq 0\}$ with X_1 having distribution μ . Third, every stationary distribution of an Ornstein–Uhlenbeck process (see **Ornstein–Uhlenbeck Processes**) belongs to the class L of ID distributions, which are self-decomposable (SD). We say that a random variable X is SD if it has the linear autoregressive property: for any $\theta \in (0, 1)$, there is a random variable ε_θ independent of X such that $X \stackrel{d}{=} \theta X + \varepsilon_\theta$.

The concept of infinite divisibility in probability was introduced in 1929 by de Fenneti. Its theory was established in the 1930s by Khintchine, Kolmogorov, and Lévy. Motivated by applications arising in different fields, from the 1960s on there was a renewed interest in the subject, in particular, among many other topics, in the study of concrete examples and subclasses of ID distributions. Historical notes and references are found in [3, 6, 8, 9].

Link with the Central Limit Theorem

The class of ID distributions is characterized as the class of possible limit laws for triangular arrays of the form $X_{n,1} + \dots + X_{n,k_n} - a_n$, where $k_n > 0$ is an increasing sequence, $X_{n,1}, \dots, X_{n,k_n}$ are independent random variable for every $n \geq 1$, a_n are normalized constants, and $\{X_{n,j}\}$ is *infinitesimal*: $\lim_{n \rightarrow \infty} \max_{1 \leq j \leq k_n} P(|X_{n,j}| > \epsilon) = 0$, for each

$\epsilon > 0$. On the other hand, the class L of SD distributions is characterized as the class of possible limit laws for normalized sequences of the form $(X_1 + \dots + X_n - a_n)/b_n$, where $X_1, X_2, \dots$ are independent random variables and a_n and $b_n > 0$ are sequences of numbers with $\lim_{n \rightarrow \infty} b_n = \infty$ and $\lim_{n \rightarrow \infty} b_{n+1}/b_n = 1$.

Lévy–Khintchine Representation

In terms of characteristic functions (see **Filtering**), a random variable X is ID if $\varphi(u) = E[e^{iuX}]$ is represented by $\varphi = (\varphi_n)^n$, where φ_n is the characteristic function of a probability distribution for every $n \geq 1$. We define the *characteristic exponent* or *cumulant function* of X by $\Psi(u) = \log \varphi(u)$. The *Lévy–Khintchine representation* establishes that a distribution function μ is ID if and only if its characteristic exponent is represented by

$$\begin{aligned} \Psi(u) = & iau - \frac{1}{2}u^2\sigma^2 \\ & + \int_{\mathbb{R}} (e^{iux} - 1 - iux1_{|x| \leq 1}) \Pi(dx), \quad u \in \mathbb{R} \end{aligned} \quad (1)$$

where $\sigma^2 \geq 0$, $a \in \mathbb{R}$ and Π is a positive measure on $\mathbb{R}$ with no atom at zero and $\int_{\mathbb{R}} \min(1, |x|^2) \Pi(dx) < \infty$. The triplet (a, σ^2, Π) is unique and is called the *generating triplet* of μ , while Π is its *Lévy measure*. When Π is zero, we have the Gaussian distribution. We speak of the purely non-Gaussian case when $\sigma^2 = 0$. When $\Pi(dx) = h(x)dx$ is absolutely continuous, we call the nonnegative function h the Lévy density of Π . Distributions in the class L are also characterized by having Lévy densities of the form $h(x) = |x|^{-1}g(x)$, where g is nondecreasing in $x < 0$ and nonincreasing in $x > 0$.

A nonnegative ID random variable is characterized by a special form of its Lévy–Khintchine representation: it is purely non-Gaussian, $\Pi(-\infty, 0) = 0$, $\int_{|x| \leq 1} |x| \Pi(dx) < \infty$, and

$$\Psi(u) = ia_0u + \int_{\mathbb{R}_+} (e^{iux} - 1) \Pi(dx) \quad (2)$$

where $a_0 \geq 0$ is called the *drift*. The associated Lévy process $\{X_t : t \geq 0\}$ is called a *subordinator*. It is a

nonnegative increasing process having characteristic exponent (2). Subordinators are useful models for random time evolutions.

Several properties of an ID random variable X are related to corresponding properties of its Lévy measure Π . For example, the k th moment $E|X|^k$ is finite if and only if $\int_{|x|>1} |x|^k \Pi(dx)$ is finite. Likewise, for the $\text{ID}_{\log}$ condition: $\int_{|x|>2} \ln|x| \Pi(dx) < \infty$ if and only if $\int_{|x|>2} \ln|x| \mu(dx) < \infty$.

The monograph [8] has a detailed study of multivariate ID distributions and their associated Lévy processes.

Classical Examples and Criteria

The Poisson distribution with mean $\lambda > 0$ is ID with Lévy measure $\Pi(B) = \lambda 1_{\{1\}}(B)$, but is not SD. A compound Poisson distribution is the law of $X = \sum_{i=1}^N Y_i$, where $N, Y_1, Y_2, \dots$ are independent random variables, N having Poisson distribution with mean λ and the Y_i 's have the same distribution G , with $G(\{0\}) = 0$. Any compound Poisson distribution is ID with Lévy measure $\Pi(B) = \lambda G(B)$. This distribution is a building block for all other ID laws, since every ID distribution is the limit of a sequence of compound Poisson distributions.

An important example of an SD law is the gamma distribution with shape parameter $\alpha > 0$ and scale parameter $\beta > 0$. It has Lévy density $h(x) = \alpha x^{-1} e^{-\beta x}$, $x > 0$. The α -stable distribution, with $0 < \alpha < 2$ and purely non Gaussian, is also SD. Its Lévy density is $h(x) = c_1 x^{-1-\alpha} dx$ on $(0, \infty)$ and $h(dx) = c_2 |x|^{-1-\alpha}$ on $(-\infty, 0)$, with $c_1 \geq 0$, $c_2 \geq 0$ and $c_1 + c_2 > 0$.

There is no explicit characterization of infinite divisibility in terms of densities or distributions. However, there are some sufficient or necessary conditions to test for infinite divisibility. A nonnegative random variable with density f is ID in any of the following cases: (i) $\log f$ is convex, (ii) f is completely monotone, or (iii) f is hyperbolically completely monotone [9]. If X is symmetric around zero, it is ID if it has a density that is completely monotone on $(0, \infty)$. For a non-Gaussian ID distribution F , its tail behavior is $-\log(1 + F(-x) - F(x)) = O(x \log x)$, when $x \rightarrow \infty$. Hence, no bounded random variable is ID and if a density has a decay of the type $c_1 \exp(-c_2 x^2)$ with some c_1, c_2 positive and if it is not Gaussian, then F is not ID. An important property

of SD distributions is that they always have densities that are unimodal.

Infinite divisibility is preserved under some mixtures of distributions. One has the surprising fact that any mixture of the exponential distribution is ID: $X \stackrel{d}{=} YV$ is ID whenever V has exponential distribution and Y is an arbitrary nonnegative random variable independent of V . The monograph [9] has a detailed study of ID mixtures.

Stochastic Integral Representations

Several classes of ID distributions are characterized by stochastic integrals (see **Stochastic Integrals**) of a nonrandom function with respect to a Lévy process [2]. The classical example is the class L that is also characterized as all the laws of $X \stackrel{d}{=} \int_0^\infty e^{-t} dZ_t$, where Z_t is a Lévy process having Lévy measure Π_Z with the $\text{ID}_{\log}$ condition. More generally, the stochastic integral $\int_0^1 \log t^{-1} dZ_t$ is well defined for every Lévy process Z_t . Denote by $B(\mathbb{R})$ the class of all the distributions of these stochastic integrals. The class $B(\mathbb{R})$ coincides with those ID laws with completely monotone Lévy density. It is also characterized as the smallest class that contains all mixtures of exponential distributions and is closed under convolution, convergence, and reflection. It is sometimes called the *Bondenson–Goldie–Steutel class of distributions*. Multivariate extensions are presented in [2].

Generalized Gamma Convolutions

The class of generalized gamma convolutions (GGCs) is the smallest class of probability distributions on $\mathbb{R}_+$ that contains all gamma distributions and is closed under convolution and convergence in distribution [6]. These laws are in the class L and have Lévy density of the form $h(x) = x^{-1} g(x)$, $x > 0$, with g a completely monotone function on $(0, \infty)$. Most of the classical distributions on $\mathbb{R}_+$ are GGC: gamma, lognormal, positive α -stable, Pareto, Student t -distribution, Gumbel, and F -distribution. Of special applicability in financial modeling is the family of generalized inverse Gaussian distributions [4, 7].

A distribution μ with characteristic exponent Ψ is GGC if and only if there exists a positive Radon

measure U on $(0, \infty)$ such that

$$\Psi(u) = ia_0u - \int_0^\infty \log\left(1 + \frac{iu}{s}\right) U(ds) \quad (3)$$

with $\int_0^1 |\log x| U(dx) < \infty$ and $\int_1^\infty U(dx)/x < \infty$. The measure U_μ is called the *Thorin measure* of μ . So, the triplet of μ is $(a_0, 0, \nu_\mu)$ where the Lévy measure is concentrated on $(0, \infty)$ and such that $\nu_\mu(dx) = dx/x \int_0^\infty e^{-xs} U_\mu(ds)$. Moreover, any GGC is the law of a Wiener-gamma integral $\int_0^\infty h(u) d\gamma_u$, where $(\gamma_t; t \geq 0)$ is the standard gamma process with Lévy measure $\nu(dx) = e^{-x}(dx/x)$ and h is a Borel function $h: \mathbb{R}_+ \rightarrow \mathbb{R}_+$ with $\int_0^\infty \log(1 + h(t))dt < \infty$. The function h is called the *Thorin function* of μ and is obtained as follows. Let $F_U(x) = \int_0^x U(dy)$ for $x \geq 0$ and let $F_U^{-1}(s)$ be the right continuous inverse of $F_U^{-1}(s)$ in the sense of composition of functions, that is $F_U^{-1}(s) = \inf\{t > 0; F_U(t) \geq s\}$ for $s \geq 0$. Then, $h(s) = 1/F_U^{-1}(s)$ for $s \geq 0$. For the positive α -stable distributions, $0 < \alpha < 1$, $h(s) = \{s\theta\Gamma(\alpha + 1)\}^{-1/\alpha}$ for a $\theta > 0$.

For distributions on $\mathbb{R}$, Thorin also introduced the class $T(\mathbb{R})$ of extended generalized gamma convolutions as the smallest class that contains the GGC and is closed under convolution, convergence in distribution, and reflection. These distributions are in the class L and are characterized by the alternative representation of their characteristic exponents

$$\begin{aligned} \Psi(u) = iua - \frac{1}{2}u^2\sigma^2 \\ - \int_{\mathbb{R}_+} \left[\ln\left(1 - \frac{iu}{x}\right) + \frac{iux}{1+x^2} \right] U(dx) \end{aligned} \quad (4)$$

where $a \in \mathbb{R}$, $\sigma^2 \geq 0$ and $U: \mathbb{R}_+ \rightarrow \mathbb{R}_+$ is a nondecreasing function with $U(0) = 0$, $\int_0^1 |\ln(x)| U(dx) < \infty$ and $\int_1^\infty x^{-2} U(dx) < \infty$. Several examples of Thorin distributions are given in [6, 9]. Any member of this class is the law of a stochastic integral $\int_0^\infty g^*(t) dZ_t$, where Z_t is a Lévy process with Z_1 satisfying the ID_{log} condition and g^* is the inverse of the incomplete gamma function $g(t) = \int_t^\infty u^{-1} e^{-u} du$ [2].

Type G Distributions

A random variable X is of *type G* if $X \stackrel{d}{=} \sqrt{V}N$, where N and V are independent random variables

with V being nonnegative ID and N having the standard normal distribution. Any type G distribution is ID and it is interpreted as the law of a random time changed Brownian motion B_V , where $\{B_t: t \geq 0\}$ is a Brownian motion independent of V . When we know the Lévy measure ρ of V , we can compute the Lévy density of X as $h(x) = (2\pi)^{-1/2} \int_{\mathbb{R}_+} s^{-1/2} e^{-\frac{1}{2s}x^2} \rho(ds)$ as well as its characteristic exponent

$$\Psi_X(u) = \int_{\mathbb{R}_+} \left(e^{-(1/2)u^2s} - 1 \right) \rho(ds) \quad (5)$$

Many classical distributions are of type G and SD: the gamma variance distribution, where V has a gamma distribution; the Student t , where V has the distribution of the reciprocal chi-square distribution and the symmetric α -stable distributions, $0 < \alpha < 2$; here V is a positive $\alpha/2$ -stable random variable, including the Cauchy distribution case $\alpha = 1$. Of special relevance in financial modeling are the normal inverse Gaussian, with V following the inverse Gaussian law [1], and the zero-mean symmetric generalized hyperbolic distributions, where V has the generalized inverse Gaussian law [5, 7]; all their moments are finite and they can accommodate heavy tails.

Tempered Stable Distributions

Tempered stable distributions (*see Tempered Stable Process*) are useful in mathematical finance as an attractive alternative to stable distributions, since they can have moments and heavy tails at the same time. Their corresponding Lévy and Ornstein–Uhlenbeck processes combines both the stable and Gaussian trends. An ID distribution on $\mathbb{R}$ is *tempered stable* if it is purely non-Gaussian and if its Lévy measure is of the form

$$\Pi(B) = \int_{\mathbb{R}} \int_0^\infty 1_B(sx) s^{-1-\alpha} g(s) ds \tau(dx) \quad (6)$$

where $0 < \alpha < 2$, g is a completely monotone function on $(0, \infty)$ and τ is a finite Borel measure on $\mathbb{R}$ such that τ has no atom at zero and $\int_{\mathbb{R}} |x|^\alpha \tau(dx) < \infty$. These distributions are in class L and constitute a proper subclass of the class of Thorin distributions $T(\mathbb{R})$.

Ornstein–Uhlenbeck Processes

There are several reasons why Ornstein–Uhlenbeck processes are of practical interest in financial stochastic modeling. These continuous-time stochastic processes offer the possibility of capturing important distributional deviations from Gaussianity and for flexible modeling of dependence structures, while retaining analytic tractability.

An *Ornstein–Uhlenbeck* (OU) process is defined as the solution X_t of a Langevin-type stochastic differential equation (SDE) $dX_t = -\lambda X_t dt + dZ_t$, where $\lambda > 0$ and Z_t is a Lévy process (*see Lévy Processes*). The process is named after L. S. Ornstein and G. E. Uhlenbeck who, in 1930, considered the classical Langevin equation when Z is a Brownian motion, and hence X_t is a Gaussian process. Historical notes, references, and details are found in [6, 7] while modeling aspects are found in [1]. At the time of writing, new extensions and applications of OU processes are thriving, many of them motivated by financial modeling.

The Gaussian OU Process

Let $\{B_t : t \geq 0\}$ be a standard Brownian motion, σ a positive constant, and x_0 a real constant. The classical OU process

$$X_t = e^{-\lambda t} x_0 + \sigma \int_0^t e^{-\lambda(t-s)} dB_s, \quad t \geq 0 \quad (1)$$

is the solution of the classical Langevin equation $dX_t = -\lambda X_t dt + \sigma dB_t$, $X_0 = x_0$. It was originally proposed as a model for the velocity of a Brownian motion and it is the continuous-time analog of the discrete-time autoregressive process AR(1). In mathematical finance, OU is used for modeling of the dynamics of interest rates and volatilities of asset prices. The process X_t is a Gaussian process with (almost surely) continuous sample paths, mean function $E(X_t) = x_0 \sigma e^{-\lambda t}$, and covariance

$$\text{Cov}(X_t, X_s) = \frac{\sigma^2}{2\lambda} (e^{-\lambda|t-s|} - e^{-\lambda(t+s)}) \quad (2)$$

For $t = s$, we obtain $\text{var}(X_t) = \frac{\sigma^2}{2\lambda} (1 - e^{-2\lambda t})$. Let N be a zero-mean Gaussian random variable with variance $\frac{\sigma^2}{2\lambda}$, independent of the Brownian motion $\{B_t : t \geq 0\}$. The process $X_t = \sigma e^{-\lambda t} \int_0^t e^{\lambda s} dB_s + N$ is a stationary Gaussian process with $\text{Cov}(X_t, X_s) = \frac{\sigma^2}{2\lambda} e^{-\lambda|t-s|}$. Moreover, X_t is a Markov process with stationary transition probability

$$P_t(x, B) = \frac{\sqrt{\lambda}}{\sigma \sqrt{\pi(1 - e^{-2\lambda t})}} \times \int_B \exp \left\{ -\frac{\lambda}{\sigma^2} \frac{(y - x e^{-\lambda t})^2}{1 - e^{-2\lambda t}} \right\} dy \quad (3)$$

Non-Gaussian OU Processes

Let $\{Z_t : t \geq 0\}$ be a Lévy process (*see Lévy Processes*). A solution of the Langevin-type SDE $dX_t = -\lambda X_t dt + dZ_t$ is a stochastic process $\{X_t : t \geq 0\}$ with right-continuous and left-limit paths satisfying the equation

$$X_t = X_0 - \lambda \int_0^t X_s ds + Z_t, \quad t \geq 0 \quad (4)$$

When X_0 is independent of $\{Z_t : t \geq 0\}$, the unique (almost surely) solution is the OU process

$$X_t = e^{-\lambda t} X_0 + \int_0^t e^{-\lambda(t-s)} dZ_s, \quad t \geq 0 \quad (5)$$

We call Z_t the *background driving Lévy process* (BDLP). Of special relevance in financial modeling is the case when Z_t is a nonnegative increasing Lévy process (a subordinator) and X_0 is nonnegative. The corresponding OU process is positive, moves up entirely by jumps, and then tails off exponentially. Hence it can be used as a variance process.

Every OU process is a time-homogeneous Markov process starting from X_0 and its transition probability $P_t(x, dy)$ is infinitely divisible (*see Infinite Divisibility*) with characteristic function (*see Filtering*)

$$\int_{\mathbb{R}} e^{iuy} P_t(x, dy) = \exp \left[i x u e^{-\lambda t} + \int_0^t \Psi(e^{-\lambda s} u) ds \right] \quad (6)$$

where Ψ is the *characteristic exponent* of the Lévy process Z_t given by the Lévy–Khintchine representation

$$\begin{aligned} \Psi(u) = iau - \frac{1}{2}u^2\sigma^2 \\ + \int_{\mathbb{R}} (e^{iux} - 1 - iux1_{|x|\leq 1})\Pi(dx), \quad u \in \mathbb{R} \end{aligned} \quad (7)$$

where $\sigma^2 \geq 0$, $a \in \mathbb{R}$, and Π , the Lévy measure, is a positive measure on $\mathbb{R}$ with $\Pi(\{0\}) = 0$ and $\int_{\mathbb{R}} \min(1, |x|^2)\Pi(dx) < \infty$. For each $t > 0$, the probability distribution of Z_t has characteristic function $\varphi_t(u) = E[e^{iuX_t}] = \exp(t\Psi(u))$. When the Lévy measure is zero, Z_t is a Brownian motion with variance σ^2 and drift a .

The Integrated OU Process

A non-Gaussian OU process X_t has the same jump times of Z_t , as one sees from equation (4). However, X_t and Z_t cobreak in the sense that a linear combination of the two does not jump. We see this by considering the continuous *integrated OU process* $I_t^X = \int_0^t X_s ds$, which has two alternative representations

$$\begin{aligned} I_t^X = \lambda^{-1} \{X_0 - X_t + Z_t\} = \lambda^{-1}(1 - e^{-\lambda t})X_0 \\ + \lambda^{-1} \int_0^t \{1 - e^{-\lambda(t-s)}\} dZ_s \end{aligned} \quad (8)$$

In the Gaussian case, the process I_t^X is interpreted as the displacement of the Brownian particle. In financial applications, I_t^X is used to model integrated variance [1].

Stationary Distribution and the Stationary OU Process

An OU process has an asymptotic distribution μ when $t \rightarrow \infty$ if it does not have too many big jumps. This is achieved if Z_1 is $\text{ID}_{\log}$: $\int_{|x|>2} \ln|x| \Pi(dx) < \infty$, where Π is the Lévy measure of Z_1 . In this case, μ does not depend on X_0 and we call μ the *stationary distribution* of X_t . Moreover, μ is a self-decomposable (SD) distribution (and hence infinitely

divisible): for any $\theta \in (0, 1)$, there is a random variable ε_θ independent of X such that $X \stackrel{d}{=} \theta X + \varepsilon_\theta$. Conversely, for every SD distribution μ there exists a Lévy process Z_t with Z_1 being $\text{ID}_{\log}$ and such that μ is the stationary distribution of the OU process driven by Z_t .

The strictly stationary OU process is defined as

$$X_t = e^{-\lambda t} \int_{-\infty}^t e^{\lambda s} dZ_s, \quad t \in \mathbb{R} \quad (9)$$

where $\{Z_t : t \in \mathbb{R}\}$ is a Lévy process constructed as follows: let $\{Z_t^1 : t \geq 0\}$ be a Lévy process with characteristic exponent Ψ_1 and let $\{Z_t^2 : t \geq 0\}$ be a Lévy process with characteristic exponent $\Psi_2(u) = \Psi_1(-u)$ and independent of Z^1 . Then $Z_t = Z_t^1$ for $t \geq 0$ and $Z_t = Z_{-t}^2$ for $t < 0$. In this case, the law of X_t is SD and conversely, for any SD law μ there exists a BDLP Z_t such that equation (9) determines a stationary OU process with distribution μ . As a result, taking $X_0 = \int_{-\infty}^0 e^{\lambda s} dZ_s$, we can always consider (5) as a strictly stationary OU process with a prescribed SD distribution μ . It is an important example of a continuous-time moving average process.

Generalizations

The monographs [6, 7] contain a detailed study of multivariate OU process, while matrix extensions are considered in [2]. Another extension is the *generalized OU process*, which has arisen in several financial applications [4, 8]. It is defined as

$$X_t = e^{-\xi_t} X_0 + e^{-\xi_t} \int_0^t e^{-\xi_{s-}} d\eta_s, \quad t \geq 0 \quad (10)$$

where $\{(\xi_t, \eta_t) : t \geq 0\}$ is a bivariate Lévy process, independent of X_0 . This process is a homogeneous Markov process starting from X_0 , and, in general, the existence of the stationary solution depends on the convergence of integrals of exponentials of Lévy processes. For example, when ξ and η are independent, and if $\xi_t \rightarrow \infty$ and $V_\infty = \int_0^\infty e^{-\xi_{s-}} d\eta_s$ is defined and finite, then the law of V_∞ is the unique stationary solution of X_t . In the dependent case, the generalized OU process admits a stationary solution that does not degenerate to a constant process if and only if $V_\infty = \lim_{t \rightarrow \infty} \int_0^t e^{-\xi_{s-}} dL_s$ exists and is finite almost surely and does not

degenerate to constant random variable, and where L_t is the accompanying Lévy process $L_t = \eta_t + \sum_{0 < s \leq t} (e^{-\Delta \xi_s} - 1) \Delta \eta_s - tE(B_1^\xi, B_1^\eta)$, where $\Delta \xi_s = \xi_s - \xi_{s-}$, with B_1^ξ, B_1^η the Gaussian parts of ξ and η respectively [3, 5].

Fractional Brownian Motion

A fractional Brownian motion (fBm) is a self-similar Gaussian process, defined as follows:

Definition 1 Let $0 < H < 1$. The Gaussian stochastic process $\{B_H(t)\}_{t \geq 0}$ satisfying the following three properties

- (i) $B_H(0) = 0$
- (ii) $E[B_H(t)] = 0$ for all $t \geq 0$,
- (iii) for all $s, t \geq 0$,

$$E[B_H(t)B_H(s)] = \frac{1}{2} (|t|^{2H} - |t-s|^{2H} + |s|^{2H}) \quad (1)$$

is called the (standard) fBm with parameter H .

The fBm has been the subject of numerous investigations, in particular, in the context of long-range dependence (often referred to as long memory). fBm was first introduced in 1940 by Kolmogorov (see **Kolmogorov, Andrei Nikolaevich**) [11], but its main properties and its relevance in many fields of application such as economics, finance, turbulence, and telecommunications were first discussed in the seminal paper of Mandelbrot (see **Mandelbrot, Benoit**) and Van Ness [12].

For historical reasons, the parameter H is also referred to as the *Hurst coefficient*. In fact, in 1951, while he was investigating the flow of the river Nile, the British hydrologist H. E. Hurst [10] noticed that his measurements showed dependence properties and, in particular, long memory behavior in the sense that they seemed to require models, whose auto-correlation functions exhibit a power law decay at large timescales. This index of dependence H always takes values between 0 and 1 and indicates relatively long-range dependence if $H > 0.5$, for example, Hurst observed $H = 0.91$ in the case of Nile level data.

If $H = 0.5$, it is obvious from equation (1) that the increments of fBm are independent and $\{B_{0.5}(t)\}_{t \in \mathbb{R}} = \{B(t)\}_{t \in \mathbb{R}}$ is ordinary Brownian motion. Moreover, fBm has *stationary increments* which, for $H \neq 0.5$, are not independent.

One can define a parametric family of fBms in terms of the *stochastic Weyl integral* (see e.g. [16], chapter 7.2). In fact, for any $a, b \in \mathbb{R}$,

$$\{B_H(t)\}_{t \in \mathbb{R}} \stackrel{d}{=} \left\{ \int_{\mathbb{R}} \left\{ a [(t-s)_+^{H-\frac{1}{2}} - (-s)_+^{H-\frac{1}{2}}] + b [(t-s)_-^{H-\frac{1}{2}} - (-s)_-^{H-\frac{1}{2}}] \right\} dB(s) \right\}_{t \in \mathbb{R}} \quad (2)$$

where $u_+ = \max(u, 0)$, $u_- = \max(-u, 0)$, and $\{B(t)\}_{t \in \mathbb{R}}$ is a two-sided standard Brownian motion constructed by taking a Brownian motion B_1 and an independent copy B_2 and setting $B(t) = B_1(t)1_{\{t \geq 0\}} - B_2(-t)1_{\{t < 0\}}$.

If we choose $a = \sqrt{\Gamma(2H+1) \sin(\pi H)} / \Gamma(H+1/2)$ and $b = 0$ in equation (2) then $\{B_H(t)\}_{t \in \mathbb{R}}$ is an fBm satisfying equation (1).

fBm admits a *Volterra type representation* $B_H(t) = \int_0^t K_H(t, s) B(ds)$, where K_H is some square integrable kernel (see [13] or [1] for details).

Properties

Many properties of fBm, like self-similarity, are given by its fractional index H .

Definition 2 A real-valued stochastic process $\{X(t)\}_{t \in \mathbb{R}}$ is self-similar with index H if for all $c > 0$, $\{X(ct)\}_{t \in \mathbb{R}} \stackrel{d}{=} c^H \{X(t)\}_{t \in \mathbb{R}}$, where $\stackrel{d}{=}$ denotes equality in distribution.

Proposition 1 Fractional Brownian motion (fBm) is self-similar with index H . Moreover, fBm is the only self-similar Gaussian process with stationary increments.

Now, we consider the increments of fBm.

Definition 3 The stationary process $\{Y(t)\}_{t \in \mathbb{R}}$ given by

$$Y(t) = B_H(t) - B_H(t-1) \quad t \in \mathbb{R} \quad (3)$$

is called *fractional Gaussian noise*.

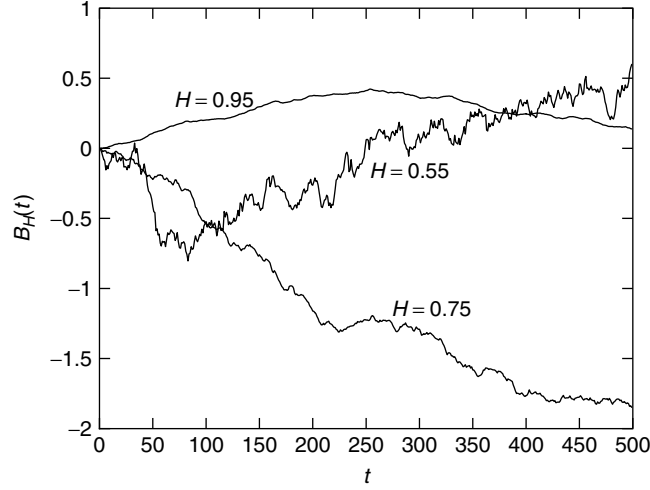

Figure 1 Various sample paths, each showing 500 points of fBm

For $n \in \mathbb{N}$, it follows by the stationarity of the increments of B_H , *such that*

$$|B_H(t) - B_H(s)| \leq c|t - s|^{H-\epsilon} \quad (6)$$

$$\begin{aligned} \rho_H(n) &:= \text{cov}(Y(k+n), Y(k)) \\ &= \frac{1}{2}(|n+1|^{2H} - 2|n|^{2H} - |n-1|^{2H}) \quad (4) \end{aligned}$$

Proposition 2

- (i) If $0 < H < 0.5$, ρ_H is negative and $\sum_{n=1}^{\infty} |\rho_H(n)| < \infty$.
- (ii) If $H = 0.5$, ρ_H equals 0, that is, the increments are independent.
- (iii) If $0.5 < H < 1$, ρ_H is positive, $\sum_{n=1}^{\infty} |\rho_H(n)| = \infty$,
and

$$\rho_H(n) \sim Cn^{2H-2}, \quad n \rightarrow \infty \quad (5)$$

Hence, for $0.5 < H < 1$ the increments of fBm are persistent or *long-range dependent*, whereas for $0 < H < 0.5$ they are said to be *antipersistent*.

Proposition 3 *The sample paths of fBm are continuous. In particular, for every $\tilde{H} < H$ there exists a modification of B_H whose sample paths are almost surely (a.s.) locally $\tilde{H}$ -Hölder continuous on $\mathbb{R}$, that is, for each trajectory, there exists a constant $c > 0$*

for any $\epsilon > 0$.

Figure 1 shows the sample paths of fBm for various values of the Hurst parameter H .

Proposition 4 *The sample paths of fBm are of finite p -variation for every $p > 1/H$ and of infinite p -variation if $p < 1/H$.*

Consequently, for $H < 0.5$ the quadratic variation is infinite. On the other hand, if $H > 0.5$ it is known that the quadratic variation of fBm is zero, whereas the total variation is infinite.

Corollary 1 *This shows that for $H \neq 1/2$, fBm cannot be a semimartingale.*

A proof of this well-known fact can be found in for example, [15] or [4].

However, since fBm is not a semimartingale one cannot use the Itô stochastic integral (*see Stochastic Integrals*) when considering integrals with respect to fBm. Recently, integration with respect to fBms has been studied extensively and various approaches have been made to define a stochastic integration theory for fBm (see e.g., [14] for a survey).

Applications in Finance

Many studies of financial time series point to long-range dependence (see **Long Range Dependence**), which indicates the potential usefulness of fBm in financial modeling (see [7] for a summary and references). One obstacle is that fBm is not a semimartingale (see **Semimartingale**), so the Itô integral cannot be used to define the gain of a self-financing portfolio as, for instance, in the Black–Scholes model (see **Black–Scholes Formula**). Various approaches have been developed for integrating fBm, some of which are as follows:

1. The *pathwise Riemann–Stieltjes fractional integral* defined by

$$\begin{aligned} & \int_0^T f(t) dB_H(t) \\ &= \lim_{|\pi| \rightarrow 0} \sum_{k=0}^{n-1} f(t_k) (B_H(t_{k+1}) - B_H(t_k)) \end{aligned} \quad (7)$$

where $\pi = \{t_k : 0 = t_0 < t_1 < \dots < t_n = T\}$ is a partition of the interval $[0, T]$ and f has bounded p -variation for some $p < 1/(1-H)$ a.s.

2. Under some regularity conditions on f , the *fractional Wick–Itô integral* has the form

$$\begin{aligned} & \int_0^T f(t) \delta B_H(t) \\ &= \lim_{|\pi| \rightarrow 0} \sum_{k=0}^{n-1} f(t_k) \diamond (B_H(t_{k+1}) - B_H(t_k)) \end{aligned} \quad (8)$$

where $\diamond$ represents the Wick product [18] and the convergence is the $L^2(\Omega)$ -convergence of random variables [2].

Whereas, the pathwise fractional integral mirrors a Stratonovich integral, the Wick–Itô–Skorohod calculus is similar to the Itô calculus, for example, integrals always have zero expectation.

The Wick–Itô integral was constructed by Duncan *et al.* [8] and later applied to finance by, for example,

Hu and Oksendal [9] in a fractional Black–Scholes pricing model in which the “gain” of a self-financing portfolio ϕ is replaced by $\int_0^T \phi(t) \delta S(t)$. However, results produced by this approach are controversial: indeed, for a piecewise constant strategy (represented by a simple predictable process) ϕ , this definition does not coincide with the capital gain of the portfolio, so the approach lacks economical interpretation [3]. An interesting study is [17], where the implications of different notions of integrals to the problem of arbitrage and self-financing condition in the fractional pricing model are considered.

An alternative is to use mixed Brownian motion, defined as the sum of a (regular) Brownian motion and an fBm with index H which, under some conditions on H , is a semimartingale [5]. Alternatively, Rogers [15] proposes to modify the behavior near zero of the kernel in equation (2) to obtain a semimartingale. In both the cases, one loses self-similarity, but conserves long-range dependence.

On the other hand, there is empirical evidence of long-range dependence in absolute returns [7], showing that it might be more interesting to use fractional processes as models of volatility rather than prices [6]. Fractional volatility processes are compatible with the semimartingale assumption for prices, so the technical obstacles discussed above do not necessarily arise when defining portfolio gain processes (see **Long Range Dependence**; **Multifractals**).

Lévy Processes

A *Lévy process* is a continuous-time stochastic process with independent and stationary increments. Lévy processes may be thought of as the continuous-time analogs of random walks. Mathematically, a Lévy process can be defined as follows.

Definition 1 An $\mathbb{R}^d$ -valued stochastic process $X = \{X_t : t \geq 0\}$ defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ is said to be a *Lévy process* if it possesses the following properties:

1. The paths of X are $\mathbb{P}$ almost surely right continuous with left limits.
2. $\mathbb{P}(X_0 = 0) = 1$.
3. For $0 \leq s \leq t$, $X_t - X_s$ is equal in distribution to X_{t-s} .
4. For $0 \leq s \leq t$, $X_t - X_s$ is independent of $\{X_u : u \leq s\}$.

Historically, Lévy processes have always played a central role in the study of stochastic processes with some of the earliest work dating back to the early 1900s. The reason for this is that, mathematically, they represent an extremely robust class of processes, which exhibit many of the interesting phenomena that appear in, for example, the theories of stochastic and potential analysis. Moreover, this in turn, together with their elementary definition, has made Lévy processes an extremely attractive class of processes for modeling in a wide variety of physical, biological, engineering, and economical scenarios. Indeed, the first appearance of particular examples of Lévy processes can be found in the foundational works of Bachelier [1, 2], concerning the use of Brownian motion, within the context of financial mathematics, and Lundberg [9], concerning the use of Poisson processes within the context of insurance mathematics.

The term *Lévy process* honors the work of the French mathematician Paul Lévy who, although not alone in his contribution, played an instrumental role in bringing together an understanding and characterization of processes with stationary and independent increments. In earlier literature, Lévy processes have been dealt with under various names. In the 1940s, Lévy himself referred to them as a subclass of *processus additifs* (additive processes), that is, processes

with independent increments. For the most part, however, research literature through the 1960s and 1970s refers to Lévy processes simply as *processes with stationary and independent increments*. One sees a change in language through the 1980s and by the 1990s the use of the term *Lévy process* had become standard.

Judging by the volume of published mathematical research articles, the theory of Lévy processes can be said to have experienced a steady flow of interest from the time of the foundational works, for example, of Lévy [8], Kolmogorov [7], Khintchine [6], and Itô [5]. However, it was arguably in the 1990s that a surge of interest in this field of research occurred, drastically accelerating the breadth and depth of understanding and application of the theory of Lévy processes. While there are many who made prolific contributions during this period, as well as thereafter, the general progression of this field of mathematics was enormously encouraged by the monographs of Bertoin [3] and Sato [10]. It was also the growing research momentum in the field of financial and insurance mathematics that stimulated a great deal of the interest in Lévy processes in recent times, thus entwining the modern theory of Lévy processes ever more with its historical roots.

Lévy Processes and Infinite Divisibility

The properties of stationary and independent increments imply that a Lévy process is a Markov process. One may show in addition that Lévy processes are strong Markov processes. From Definition 1 alone it is otherwise difficult to understand the richness of the class of Lévy processes. To get a better impression in this respect, it is necessary to introduce the notion of an *infinitely divisible* distribution. Generally, an $\mathbb{R}^d$ -valued random variable Θ has an infinitely divisible distribution if for each $n = 1, 2, \dots$ there exists a sequence of i.i.d. random variables $\Theta_{1,n}, \dots, \Theta_{n,n}$ such that

$$\Theta \stackrel{d}{=} \Theta_{1,n} + \dots + \Theta_{n,n} \quad (1)$$

where $\stackrel{d}{=}$ is equality in distribution. Alternatively, this relation can be expressed in terms of characteristic exponents. That is to say, if Θ has characteristic exponent $\Psi(u) := -\log \mathbb{E}(e^{iu \cdot \Theta})$, then Θ is infinitely divisible if and only if for all $n \geq 1$ there exists a characteristic exponent of a probability distribution, say Ψ_n , such that $\Psi(u) = n\Psi_n(u)$ for all $u \in \mathbb{R}^d$.

It turns out that Θ has an infinitely divisible distribution if and only if there exists a triple (a, Σ, Π) , where $a \in \mathbb{R}^d$, Σ is a $d \times d$ matrix whose eigenvalues are all nonnegative, and Π is a measure concentrated on $\mathbb{R}^d \setminus \{0\}$ satisfying $\int_{\mathbb{R}^d} (1 \wedge |x|^2) \Pi(dx) < \infty$, such that

$$\Psi(u) = ia \cdot u + \frac{1}{2} u \cdot \Sigma u + \int_{\mathbb{R}^d} (1 - e^{iu \cdot x} + iu \cdot x \mathbf{1}_{(|x| < 1)}) \Pi(dx) \quad (2)$$

for every $\theta \in \mathbb{R}^d$. Here, we use the notation $u \cdot x$ for the Euclidian inner product and $|x|$ for Euclidian distance. The measure Π is called the *Lévy (characteristic) measure* and it is unique. The identity in equation (2) is known as the *Lévy–Khintchine formula*.

The link between a Lévy processes and infinitely divisible distributions becomes clear when one notes that for each $t > 0$ and any $n = 1, 2, \dots$,

$$X_t = X_{t/n} + (X_{2t/n} - X_{t/n}) + \dots + (X_t - X_{(n-1)t/n}) \quad (3)$$

As a result of the fact that X has stationary independent Increments, it follows that X_t is infinitely divisible.

It can be deduced from the above observation that any Lévy process has the property that for all $t \geq 0$

$$\mathbb{E}(e^{iu \cdot X_t}) = e^{-t\Psi(u)} \quad (4)$$

where $\Psi(\theta) := \Psi_1(\theta)$ is the characteristic exponent of X_1 , which has an infinitely divisible distribution. The converse of this statement is also true, thus constituting the Lévy–Khintchine formula for Lévy processes.

Theorem 1 (Lévy–Khintchine formula for Lévy processes). *$a \in \mathbb{R}^d$, Σ is a $d \times d$ matrix whose eigenvalues are all nonnegative, and Π is a measure concentrated on $\mathbb{R}^d \setminus \{0\}$ satisfying $\int_{\mathbb{R}^d} (1 \wedge |x|^2) \Pi(dx) < \infty$. Then there exists a Lévy process having characteristic exponent*

$$\Psi(u) = ia \cdot u + \frac{1}{2} u \cdot \Sigma u + \int_{\mathbb{R}^d} (1 - e^{iu \cdot x} + iu \cdot x \mathbf{1}_{(|x| < 1)}) \Pi(dx) \quad (5)$$

Two fundamental examples of Lévy processes, which are shown in the next section to form the “building blocks” of all the other Lévy processes, are Brownian motion and compound Poisson processes. A Brownian motion is the Lévy process associated with the characteristic exponent

$$\Psi(u) = \frac{1}{2} u \cdot \Sigma u \quad (6)$$

and therefore has increments over time periods of length t , which are Gaussian distributed with covariance matrix Σt . It can be shown that, up to the addition of a linear drift, Brownian motions are the only Lévy processes that have continuous paths.

A compound Poisson process is the Lévy process associated with the characteristic exponent:

$$\Psi(u) = \int_{\mathbb{R}^d} (1 - e^{iu \cdot x}) \lambda F(dx) \quad (7)$$

where $\lambda > 0$ and F is a probability distribution. Such processes may be described pathwise by the piecewise linear process:

$$\sum_{i=1}^{N_t} \xi_i, \quad t \geq 0 \quad (8)$$

where $\{\xi_i : i \geq 1\}$ are a sequence of i.i.d. random variables with common distribution F , and $\{N_t : t \geq 0\}$ is a Poisson process with rate λ ; the latter is the process with initial value zero and with unit increments whose interarrival times are independent and exponentially distributed with parameter λ .

It is a straightforward exercise to show that the sum of any finite number of independent Lévy processes is also a Lévy process. Under some circumstances, one may show that a countably infinite sum of Lévy processes also converges in an appropriate sense to a Lévy process. This idea forms the basis of the Lévy–Itô decomposition, discussed in the next section, where, as alluded to above, the Lévy processes that are summed together are either a Brownian motion with drift or a compound Poisson process with drift.

The Lévy–Itô Decomposition

Hidden in the Lévy–Khintchine formula is a representation of the path of a given Lévy process. Every

Lévy process may always be written as the independent sum of up to a countably infinite number of other Lévy processes, at most one of which will be a linear Brownian motion and the remaining processes will be compound Poisson processes with drift.

Let Ψ be the characteristic exponent of some infinitely divisible distribution with associated triple (a, Σ, Π) . The necessary assumption that $\int_{\mathbb{R}^d} (1 \wedge |x|^2) \Pi(dx) < \infty$ implies that $\Pi(A) < \infty$ for all Borel A such that 0 is in the interior of A^c and, in particular, that $\Pi(\{x : |x| \geq 1\}) \in [0, \infty)$. With this in mind, it is not difficult to see that, after some simple reorganization, for $u \in \mathbb{R}^d$, the Lévy–Khintchine formula can be written in the form

$$\begin{aligned} \Psi(\theta) = & \left\{ iu \cdot a + \frac{1}{2} u \cdot \Sigma u \right\} \\ & + \left\{ \lambda_0 \int_{|x| \geq 1} (1 - e^{iu \cdot x}) F_0(dx) \right\} \\ & + \sum_{n \geq 1} \left\{ \lambda_n \int_{2^{-n} \leq |x| < 2^{-(n-1)}} (1 - e^{iu \cdot x}) F_n(dx) \right. \\ & \left. + i \lambda_n u \cdot \left(\int_{2^{-n} \leq |x| < 2^{-(n-1)}} x F_n(dx) \right) \right\} \quad (9) \end{aligned}$$

where $\lambda_0 = \Pi(\{x : |x| \geq 1\})$, $F_0(dx) = \Pi(dx)/\lambda_0$, and for $n = 1, 2, 3, \dots$, $\lambda_n = \Pi(\{x : 2^{-n} \leq |x| < 2^{-(n-1)}\})$ and $F_n(dx) = \Pi(dx)/\lambda_n$ (with the understanding that the n th integral is absent if $\lambda_n = 0$). This decomposition suggests that the Lévy process $X = \{X_t : t \geq 0\}$ associated with Ψ may be written as the independent sum:

$$X_t = Y_t + X_t^{(0)} + \lim_{k \uparrow \infty} \sum_{n=1}^k X_t^{(n)}, \quad t \geq 0 \quad (10)$$

where

$$Y_t = B_t^\Sigma - at, \quad t \geq 0 \quad (11)$$

with $\{B_t^\Sigma : t \geq 0\}$ a d -dimensional Brownian motion with covariance matrix Σ ,

$$X_t^{(0)} = \sum_{i=1}^{N_t^{(0)}} \xi_i^{(0)}, \quad t \geq 0 \quad (12)$$

with $\{N_t^{(0)} : t \geq 0\}$ as a Poisson process with rate λ_0 and $\{\xi_i^{(0)} : i \geq 1\}$ are independent and identically

distributed with common distribution $F_0(dx)$ concentrated on $\{x : |x| \geq 1\}$ and for $n = 1, 2, 3, \dots$

$$X_t^{(n)} = \sum_{i=1}^{N_t^{(n)}} \xi_i^{(n)} - \lambda_n t \int_{2^{-n} \leq |x| < 2^{-(n-1)}} x F_n(dx), \quad t \geq 0 \quad (13)$$

with $\{N_t^{(n)} : t \geq 0\}$ as a Poisson process with rate λ_n and $\{\xi_i^{(n)} : i \geq 1\}$ are independent and identically distributed with common distribution $F_n(dx)$ concentrated on $\{x : 2^{-n} \leq |x| < 2^{-(n-1)}\}$. The limit in equation (10) needs to be understood in the appropriate context, however.

It is a straightforward exercise to deduce that $X_t^{(n)}$ is a square integrable martingale on account of the fact that it is a centered compound Poisson process together with the fact that x^2 is integrable in the neighborhood of the origin against the measure Π . It is not difficult to see that $\sum_{n=1}^k X_t^{(n)}$ is also a square integrable martingale. The convergence of $\sum_{n=1}^k X_t^{(n)}$ as $k \uparrow \infty$ can happen in one of the two ways. The two quantities

$$\begin{aligned} \lim_{k \uparrow \infty} \sum_{n=1}^k \sum_{i=1}^{N_t^{(n)}} |\xi_i^{(n)}| \quad \text{and} \\ \lim_{k \uparrow \infty} \sum_{n=1}^k \int_{2^{-n} \leq |x| < 2^{-(n-1)}} |x| \lambda_n F_n(dx) \quad (14) \end{aligned}$$

are either simultaneously finite or infinite (for all $t > 0$), where the random limit is understood in the almost sure sense. When both are finite, that is to say, when $\int_{|x| < 1} |x| \Pi(dx) < \infty$, then $\sum_{n=1}^\infty X_t^{(n)}$ is well defined as the difference of a stochastic processes with jumps and a linear drift. Conversely when $\int_{|x| < 1} |x| \Pi(dx) = \infty$, it can be shown that, thanks to the assumption, $\int_{|x| < 1} |x|^2 \Pi(dx) < \infty$, $\sum_{n=1}^k X_t^{(n)}$ converges uniformly over finite time horizons in the L^2 norm as $k \uparrow \infty$. In that case, the two exploding limits in equation (14) compensate each other in the right way for their difference to converge in the prescribed sense.

Either way, the properties of stationary and independent increments and almost surely right continuous paths with left limits that belong to $\sum_{n=1}^k X_t^{(n)}$ as a finite sum of Lévy processes are also inherited by the limiting process as $k \uparrow \infty$. It is also the case that the limiting Lévy process is also a square integrable

martingale just as the elements of the approximating sequence are.

Path Variation

Consider any function $f : [0, \infty) \rightarrow \mathbb{R}^d$. Given any partition $\mathcal{P} = \{a = t_0 < t_1 < \dots < t_n = b\}$ of the bounded interval $[a, b]$, define the variation of f over $[a, b]$ with partition $\mathcal{P}$ by

$$V_{\mathcal{P}}(f, [a, b]) = \sum_{i=1}^n |f(t_i) - f(t_{i-1})| \quad (15)$$

The function f is said to be of bounded variation over $[a, b]$ if

$$V(f, [a, b]) := \sup_{\mathcal{P}} V_{\mathcal{P}}(f, [a, b]) < \infty \quad (16)$$

where the supremum is taken over all partitions of $[a, b]$. Moreover, f is said to be of *bounded variation* if the above inequality is valid for all bounded intervals $[a, b]$. If $V(f, [a, b]) = \infty$ for all bounded intervals $[a, b]$, then f is said to be of *unbounded variation*.

For any given stochastic process $X = \{X_t : t \geq 0\}$, we may adopt these notions in the almost sure sense. So, for example, the statement “ X is a process of bounded variation” (or “has paths of bounded variation”) simply means that as a random mapping, $X : [0, \infty) \rightarrow \mathbb{R}^d$ is of bounded variation almost surely.

In the case that X is a Lévy process, the Lévy–Itô decomposition also gives the opportunity to establish a precise characterization of the path variation of a Lévy process. Since any Lévy process may be written as the independent sum as in equation (10) and any d -dimension Brownian motion is known to have paths of unbounded variation, it follows that any Lévy process for which $\Sigma \neq 0$ has unbounded variation. In the case that $\Sigma = 0$, since the paths of the component $X^{(0)}$ in equation (10) are independent and clearly of bounded variation (they are piecewise linear), the path variation of X is characterized by the way in which the component $\sum_{n=1}^k X_t^{(n)}$ converges. In the case that

$$\int_{|x|<1} |x| \Pi(dx) < \infty \quad (17)$$

the Lévy process X will thus be of bounded variation and otherwise, when the above integral is infinite, the paths are of unbounded variation.

In the case that $d = 1$, as an extreme case of a Lévy process with bounded variation, it is possible that the process X has nondecreasing paths, in which case it is called a *subordinator*. As is apparent from the Lévy–Itô decomposition (9), this will necessarily occur when $\Pi(-\infty, 0) = 0$,

$$\int_{(0,1)} x \Pi(dx) < \infty \quad (18)$$

and $\Sigma = 0$. In that case, reconsidering the decomposition (10), one may identify

$$X_t = \left(-a - \int_{(0,1)} x \Pi(dx) \right) t + \lim_{k \uparrow \infty} \sum_{n=1}^k \sum_{i=1}^{N_t^{(n)}} \xi_i^{(n)} \quad (19)$$

On account of the assumption $\Pi(-\infty, 0) = 0$, all the jumps $\xi_i^{(n)}$ are nonnegative. Hence, it is also a necessary condition that

$$-a - \int_{(0,1)} x \Pi(dx) \geq 0 \quad (20)$$

for X to have nondecreasing paths. These necessary conditions are also sufficient.

Lévy Processes as Semimartingales

Recall that a semimartingale with respect to a given filtration $\mathbb{F} := \{\mathcal{F}_t : t \geq 0\}$ is defined as the sum of an $\mathbb{F}$ -local martingale and an $\mathbb{F}$ -adapted process of bounded variation. The importance of semimartingales is that they form a natural class of stochastic processes with respect to which one may construct a stochastic integral and thereafter perform calculus. Moreover, the theory of stochastic calculus plays a significant role in mathematical finance as it can be used as a key ingredient in justifying the pricing and hedging of derivatives in markets where risky assets are modeled as positive semimartingales.

A popular choice of model for risky assets in recent years has been the exponential of a Lévy process (see **Exponential Lévy Models**). Lévy processes have also been used as building blocks in more complex stochastic models for prices, such as stochastic

volatility models with jumps (*see* **Barndorff-Nielsen and Shephard (BNS) Models**) and time-changed Lévy models (*see* **Time-changed Lévy Process**). The monograph of Cont and Tankov [4] gives an extensive exposition on these types of models. Thanks to Itô's formula for semimartingales, the exponential of a Lévy process is a semimartingale when it can be shown that a Lévy process is a semimartingale. However, reconsidering equation (10) and recalling that B^Σ and $\lim_{k \uparrow \infty} \sum_{n=1}^k X^{(n)}$ are martingales and that $X^{(0)} - a \cdot$ is an adapted process with bounded variation paths, it follows immediately that any Lévy process is a semimartingale.

Wiener–Hopf Decomposition

A fundamental part of the theory of random walks and Lévy processes is a set of conclusions, which, in modern times, are loosely referred to as *the Wiener–Hopf factorization*. Historically, the identities around which the Wiener–Hopf factorization is centered are the culmination of a number of works that include [2–4, 6–8, 14–17], and many others; although the analytical roots of the so-called Wiener–Hopf method go much further back than these probabilistic references; see, for example, [9, 13]. The importance of the Wiener–Hopf factorization for either a random walk or a Lévy process is that it characterizes the range of the running maximum of the process as well as the times at which new maxima are attained. We deal with the Wiener–Hopf factorization for random walks before moving to the case of Lévy processes. The discussion very closely follows the ideas of [6, 7]. Indeed, for the case of random walks, we shall not deter from providing proofs as their penetrating and yet elementary nature reveals a simple path decomposition that is arguably more fundamental than the Wiener–Hopf factorization itself. The Wiener–Hopf factorization for Lévy processes is essentially a technical variant of the case for random walks and we only state it without proof.

Random Walks and Infinite Divisibility

Suppose that $\{\xi_i : i = 1, 2, \dots\}$ are a sequence of $\mathbb{R}$ -valued independent and identically distributed (i.i.d.) random variables defined on the common probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with common distribution function F . Let

$$S_0 = 0 \text{ and } S_n = \sum_{i=1}^n \xi_i \quad (1)$$

The process $S = \{S_n : n \geq 0\}$ is called a (*real valued*) random walk. For convenience, we make a number of assumptions on F . First,

$$\min\{F(0, \infty), F(-\infty, 0)\} > 0 \quad (2)$$

meaning that the random walk may experience both positive and negative jumps, and second, F has no atoms. In the prevailing analysis, we repeatedly refer

to general and specific classes of infinitely divisible random variables (see **Infinite Divisibility**). An $\mathbb{R}^d$ -valued random variable X is infinitely divisible if for each $n = 1, 2, 3, \dots$

$$X \stackrel{d}{=} X_{(1,n)} + \dots + X_{(n,n)} \quad (3)$$

where $\{X_{(i,n)} : i = 1, \dots, n\}$ are i.i.d. distributed and the equality is in the distribution. In other words, if μ is the characteristic function of X , then for each $n = 1, 2, 3, \dots$ we have $\mu = (\mu_n)^n$, where μ_n is the characteristic function of some $\mathbb{R}^d$ -valued random variable.

In general, if X is any $\mathbb{R}^d$ -valued random variable that is also infinitely divisible, then for each $\theta \in \mathbb{R}^d$, $E(e^{i\theta \cdot X}) = e^{-\Psi(\theta)}$ where

$$\begin{aligned} \Psi(\theta) = & ia \cdot \theta + \frac{1}{2} Q(\theta) \\ & + \int_{\mathbb{R}^d} (1 - e^{i\theta \cdot x} + i\theta \cdot x \mathbf{1}_{(|x| < 1)}) \Pi(dx) \end{aligned} \quad (4)$$

where $a \in \mathbb{R}^d$, Q is a positive semidefinite quadratic form on $\mathbb{R}^d$ and Π is a measure supported in $\mathbb{R}^d \setminus \{0\}$ such that

$$\int_{\mathbb{R}^d} 1 \wedge |x|^2 \Pi(dx) < \infty \quad (5)$$

Here, $|\cdot|$ is Euclidean distance and, for $a, b \in \mathbb{R}^d$, $a \cdot b$ is the usual Euclidean inner product.

A special example of an infinitely divisible distribution is the geometric distribution. The symbol Γ_p always denotes a geometric distribution with parameter $p \in (0, 1)$ defined on $(\Omega, \mathcal{F}, \mathbb{P})$. In particular,

$$P(\Gamma_p = k) = pq^k, \quad k = 0, 1, 2, \dots \quad (6)$$

where $q = 1 - p$. The geometric distribution has the following properties that are worth recalling for the forthcoming discussion. First,

$$P(\Gamma_p \geq k) = q^k \quad (7)$$

and, second, the lack-of-memory property:

$$\begin{aligned} P(\Gamma_p \geq n + m | \Gamma_p \geq m) &= P(\Gamma_p \geq n), \\ n, m &= 0, 1, 2, \dots \end{aligned} \quad (8)$$

A more general class of infinitely divisible distributions than the latter, which will shortly be of use,

are those that may be expressed as the distribution of a random walk sampled at an independent and geometrically distributed time; $S_{\Gamma_p} = \sum_{i=1}^{\Gamma_p} \xi_i$. (Note, we interpret $\sum_{i=1}^0$ as the empty sum). To justify the previous claim, a straightforward computation shows that for each $n = 1, 2, 3, \dots$

$$\begin{aligned} \mathbb{E}(e^{i\theta S_{\Gamma_p}}) &= \left(\left(\frac{p}{1 - q \mathbb{E}(e^{i\theta \xi_1})} \right)^{\frac{1}{n}} \right)^n \\ &= \mathbb{E}(e^{i\theta S_{\Lambda_{1/n,p}}}) \end{aligned} \quad (9)$$

where $\Lambda_{1/n,p}$ is a negative binomial random variable with parameters $1/n$ and p , which is independent of S . The latter has distribution mass function

$$\mathbb{P}(\Lambda_{1/n,p} = k) = \frac{1}{k!} \frac{\Gamma(k+1/n)}{\Gamma(1/n)} p^{1/n} q^k \quad (10)$$

for $k = 0, 1, 2, \dots$

Wiener–Hopf Factorization for Random Walks

We now turn our attention to the Wiener–Hopf factorization. Fix $0 < p < 1$ and define

$$G = \inf \left\{ k = 0, 1, \dots, \Gamma_p : S_k = \max_{j=0,1,\dots,\Gamma_p} S_j \right\} \quad (11)$$

where Γ_p is a geometrically distributed random variable with parameter p , which is independent of the random walk S , that is, G is the first visit of S to its maximum over the time period $\{0, 1, \dots, \Gamma_p\}$. Now define

$$N = \inf\{n > 0 : S_n > 0\} \quad (12)$$

In other words, the first visit of S to $(0, \infty)$ after time 0.

Theorem 1 (Wiener–Hopf Factorization for Random Walks) Assume all of the notation and conventions above.

- (i) (G, S_G) is independent of $(\Gamma_p - G, S_{\Gamma_p} - S_G)$ and both pairs are infinitely divisible.

- (ii) For $0 < s \leq 1$ and $\theta \in \mathbb{R}$

$$\begin{aligned} E(s^G e^{i\theta S_G}) \\ = \exp \left\{ - \int_{(0,\infty)} \sum_{n=1}^{\infty} (1-s^n e^{i\theta x}) q^n \frac{1}{n} F^{*n}(dx) \right\} \end{aligned} \quad (13)$$

- (iii) For $0 < s \leq 1$ and $\theta \in \mathbb{R}$

$$\begin{aligned} E(s^N e^{i\theta S_N}) \\ = 1 - \exp \left\{ - \int_{(0,\infty)} \sum_{n=1}^{\infty} s^n e^{i\theta x} \frac{1}{n} F^{*n}(dx) \right\} \end{aligned} \quad (14)$$

Note that the third part of the Wiener–Hopf factorization characterizes what is known as the *ladder height process* of the random walk S . The latter is the bivariate random walk $(T, H) := \{(T_n, H_n) : n = 0, 1, 2, \dots\}$ where $(T_0, H_0) = (0, 0)$, and otherwise for $n = 1, 2, 3, \dots$,

$$T_n = \begin{cases} \min \{k \geq 1 : S_{T_{n-1}+k} > H_{n-1}\} & \text{if } T_{n-1} < \infty \\ \infty & \text{if } T_{n-1} = \infty \end{cases}$$

and

$$H_n = \begin{cases} S_{T_n} & \text{if } T_n < \infty \\ \infty & \text{if } T_n = \infty \end{cases} \quad (15)$$

That is to say, the process (T, H) , until becoming infinite in value, represents the times and positions of the running maxima of S , the so-called ladder times and ladder heights. It is not difficult to see that T_n is a stopping time for each $n = 0, 1, 2, \dots$ and hence thanks to the i.i.d. increments of S , the increments of (T, H) are i.i.d. with the same law as the pair (N, S_N) .

Proof (i) The path of the random walk may be broken into $\nu \in \{0, 1, 2, \dots\}$ finite (or completed) excursions from the maximum followed by an additional excursion, which straddles the random time Γ_p . Here, we understand the use of the word straddle to mean that if ℓ is the index of the left end point of the straddling excursion then $\ell \leq \Gamma_p$. By the strong Markov property for random walks and lack of memory, the completed excursions must have the same law, namely, that of a random walk sampled on the time points $\{1, 2, \dots, N\}$ conditioned on the

event that $\{N \leq \Gamma_p\}$ and hence ν is geometrically distributed with parameter $1 - P(N \leq \Gamma_p)$. Mathematically, we express

$$(G, S_G) = \sum_{i=1}^{\nu} (N^{(i)}, H^{(i)}) \quad (16)$$

where the pairs $\{(N^{(i)}, H^{(i)}) : i = 1, 2, \dots\}$ are independent having the same distribution as (N, S_N) conditioned on $\{N \leq \Gamma_p\}$. Note also that G is the sum of the lengths of the latter conditioned excursions and S_G is the sum of the respective increment of the terminal value over the initial value of each excursion. In other words, (G, S_G) is the component-wise sum of ν independent copies of (N, S_N) (with $(G, S_G) = (0, 0)$ if $\nu = 0$). Infinite divisibility follows as a consequence of the fact that (G, S_G) is a geometric sum of i.i.d. random variables. The independence of (G, S_G) and $(\Gamma_p - G, S_{\Gamma_p} - S_G)$ is immediate from the decomposition described above.

Feller's classic duality lemma (cf [3]) for random walks says that for any $n = 0, 1, 2, \dots$ (which may later be randomized with an independent geometric distribution), the independence and common distribution of increments implies that $\{S_{n-k} - S_n : k = 0, 1, \dots, n\}$ has the same law as $\{-S_k : k = 0, 1, \dots, n\}$. In the current context, the duality lemma also implies that the pair $(\Gamma_p - G, S_{\Gamma_p} - S_G)$ is equal in distribution to (D, S_D) where

$$D := \sup \left\{ k = 0, 1, \dots, \Gamma_p : S_k = \min_{j=0,1,\dots,\Gamma_p} S_j \right\} \quad (17)$$

(ii) Note that, as a geometric sum of i.i.d. random variables, the pair (Γ_p, S_{Γ_p}) is infinitely divisible for $s \in (0, 1)$ and $\theta \in \mathbb{R}$, let $q = 1 - p$ and also that, on one hand,

$$\begin{aligned} E(s^{\Gamma_p} e^{i\theta S_{\Gamma_p}}) &= E\left(E(s e^{i\theta S_1})^{\Gamma_p}\right) \\ &= \sum_{k \geq 0} p (q s E(e^{i\theta S_1}))^k \\ &= \frac{p}{1 - q s E(e^{i\theta S_1})} \end{aligned} \quad (18)$$

and, on the other hand, with the help of Fubini's Theorem,

$$\begin{aligned} &\exp \left\{ - \int_{\mathbb{R}} \sum_{n=1}^{\infty} (1 - s^n e^{i\theta x}) q^n \frac{1}{n} F^{*n}(dx) \right\} \\ &= \exp \left\{ - \sum_{n=1}^{\infty} (1 - s^n E(e^{i\theta S_n})) q^n \frac{1}{n} \right\} \\ &= \exp \left\{ - \sum_{n=1}^{\infty} (1 - s^n E(e^{i\theta S_1})^n) q^n \frac{1}{n} \right\} \\ &= \exp \{ \log(1 - q) - \log(1 - q s E(e^{i\theta S_1})) \} \\ &= \frac{p}{1 - q s E(e^{i\theta S_1})} \end{aligned} \quad (19)$$

where, in the last equality, we have applied the Mercator–Newton series expansion of the logarithm. Comparing the conclusions of the last two series of equalities, the required expression for $E(s^{\Gamma_p} e^{i\theta S_{\Gamma_p}})$ follows. The Lévy measure mentioned in equation (4) is thus identifiable as

$$\Pi(dy, dx) = \sum_{n=1}^{\infty} \delta_{\{n\}}(dy) F^{*n}(dx) \frac{1}{n} q^n \quad (20)$$

for $(y, x) \in \mathbb{R}^2$.

We know that (Γ_p, S_{Γ_p}) may be written as the independent sum of (G, S_G) and $(\Gamma_p - G, S_{\Gamma_p} - S_G)$, where both are infinitely divisible. Further, the former has Lévy measure supported on $\{1, 2, \dots\} \times (0, \infty)$ and the latter has Lévy measure supported on $\{1, 2, \dots\} \times (-\infty, 0)$. In addition, $E(s^G e^{i\theta S_G})$ extends to the upper half of the complex plane in θ (and is continuous on the real axis) and $E(s^{\Gamma_p - G} e^{i\theta(S_{\Gamma_p} - S_G)})$ extends to the lower half of the complex plane in θ (and is continuous on the real axis).^a Taking account of equation (4), this forces the factorization of the expression for $E(s^{\Gamma_p} e^{i\theta S_{\Gamma_p}})$ in such a way that

$$E(s^G e^{i\theta S_G}) = e^{- \int_{(0, \infty)} \sum_{n=1}^{\infty} (1 - s^n e^{i\theta x}) q^n \frac{1}{n} F^{*n}(dx) / n} \quad (21)$$

(iii) Note that the path decomposition given in part (i) shows that

$$E(s^G e^{i\theta S_G}) = E\left(s^{\sum_{i=1}^{\nu} N^{(i)}} e^{i\theta \sum_{i=1}^{\nu} H^{(i)}}\right) \quad (22)$$

where the pairs $\{(N^{(i)}, H^{(i)}) : i = 1, 2, \dots\}$ are independent having the same distribution as (N, S_N) conditioned on $\{N \leq \Gamma_p\}$. Hence, we have

$$\begin{aligned}
 & E(s^G e^{i\theta S_G}) \\
 &= \sum_{k \geq 0} P(N > \Gamma_p) P(N \leq \Gamma_p)^k \\
 &\quad \times E\left(s^{\sum_{i=1}^k N^{(i)}} e^{i\theta \sum_{i=1}^k H^{(i)}}\right) \\
 &= \sum_{k \geq 0} P(N > \Gamma_p) P(N \leq \Gamma_p)^k E(s^N e^{i\theta S_N} | N \leq \Gamma_p)^k \\
 &= \sum_{k \geq 0} P(N > \Gamma_p) E(s^N e^{i\theta S_N} \mathbf{1}_{(N \leq \Gamma_p)})^k \\
 &= \sum_{k \geq 0} P(N > \Gamma_p) E((qs)^N e^{i\theta S_N})^k \\
 &= \frac{P(N > \Gamma_p)}{1 - E((qs)^N e^{i\theta S_N})} \tag{23}
 \end{aligned}$$

Note that in the fourth equality we use the fact that $P(\Gamma_p \geq n) = q^n$.

The required equality to be proved follows by setting $s = 0$ in equation (21) to recover

$$P(N > \Gamma_p) = \exp \left\{ - \int_{(0, \infty)} \sum_{n=1}^{\infty} \frac{q^n}{n} F^{*n}(\mathrm{d}x) \right\} \tag{24}$$

and then plugging this back into the right-hand side of equation (23) and rearranging.

Lévy Processes and Infinite Divisibility

A (one-dimensional) stochastic process $X = \{X_t : t \geq 0\}$ is called a *Lévy process* (see **Lévy Processes**) on some probability space $(\Omega, \mathcal{F}, \mathbb{P})$ if

1. X has paths that are $\mathbb{P}$ -almost surely right continuous with left limits;
2. given $0 \leq s \leq t < \infty$, $X_t - X_s$ is independent of $\{X_u : u \leq s\}$;
3. given $0 \leq s \leq t < \infty$, $X_t - X_s$ is equal in distribution to X_{t-s} ; and

$$\mathbb{P}(X_0 = 0) = 1 \tag{25}$$

It is easy to deduce that if X is a Lévy process, then for each $t > 0$ the random variable X_t is infinitely divisible. Indeed, one may also show *via* a straightforward computation that

$$\mathbb{E}(e^{i\theta X_t}) = e^{-\Psi(\theta)t} \text{ for all } \theta \in \mathbb{R}, \quad t \geq 0 \tag{26}$$

where, in its most general form, Ψ takes the form given in equation (4). Conversely, it can also be shown that given a Lévy–Khintchine exponent (4) of an infinitely divisible random variable, there exists a Lévy process that satisfies equation (26). In the special case that the Lévy–Khintchine exponent Ψ belongs to that of a positive-valued infinitely divisible distribution, it follows that the increments of the associated Lévy process must be positive and hence its paths are necessarily monotone increasing. In full generality, a Lévy process may be naively thought of as the independent sum of a linear Brownian motion plus an independent process with discontinuities in its path, which, in turn, may be seen as the limit (in an appropriate sense) of the partial sums of a sequence of compound Poisson processes with drift. The book by Bertoin [1] gives a comprehensive account of the above details.

The definition of a Lévy process suggests that it may be thought of as a continuous-time analog of a random walk. Let us introduce the exponential random variable with parameter p , denoted by $\mathbf{e}_p$, which henceforth is assumed to be independent of all other random quantities under discussion and defined on the same probability space. Like the geometric distribution, the exponential distribution also has a lack-of-memory property in the sense that for all $0 \leq s, t < \infty$ we have $\mathbb{P}(\mathbf{e}_p > t + s | \mathbf{e}_p > t) = \mathbb{P}(\mathbf{e}_p > s) = e^{-ps}$. Moreover, $\mathbf{e}_p$, and, more generally, $X_{\mathbf{e}_p}$, is infinitely divisible. Indeed, straightforward computations show that for each $n = 1, 2, 3, \dots$

$$\mathbb{E}(e^{i\theta X_{\mathbf{e}_p}}) = \left(\left(\frac{p}{p + \Psi(\theta)} \right)^{\frac{1}{n}} \right)^n = \mathbb{E}(e^{i\theta X_{\gamma_{1/n, p}}})^n \tag{27}$$

where $\gamma_{1/n, p}$ is a gamma distribution with parameters $1/n$ and p , which is independent of X . The latter has distribution

$$\mathbb{P}(\gamma_{1/n, p} \in \mathrm{d}x) = \frac{p^{1/n}}{\Gamma(1/n)} x^{-1+1/n} e^{-px} \mathrm{d}x \tag{28}$$

for $x > 0$.

Wiener–Hopf Factorization for Lévy Processes

The Wiener–Hopf factorization for a one-dimensional Lévy processes is slightly more technical than for random walks but, in principle, appeals to essentially the same ideas that have been exhibited in the above exposition of the Wiener–Hopf factorization for random walks. In this section, therefore, we give only a statement of the Wiener–Hopf factorization. The reader who is interested in the full technical details is directed primarily to the article by Greenwood and Pitman [6] for a natural and insightful probabilistic presentation (in the author’s opinion). Alternative accounts based on the aforementioned article can be found in the books by Bertoin [1] and Kyprianou [12], and derivation of the Wiener–Hopf factorization for Lévy processes from the Wiener–Hopf factorization for random walks can be found in [18].

Before proceeding to the statement of the Wiener–Hopf factorization, we first need to introduce the *ladder process* associated with any Lévy process X . Here, we encounter more subtleties than for the random walk. Consider the range of the times and positions at which the process X attains new maxima. That is to say, the random set $\{(t, \bar{X}_t) : \bar{X}_t = X_t\}$ where $\bar{X}_t = \sup_{s \leq t} X_s$ is the running maximum. It turns out that this range is equal in law to the range of a killed bivariate subordinator $(\tau, H) = \{(\tau_t, H_t) : t < \zeta\}$, where the killing time ζ is an independent and exponentially distributed random variable with some rate $\lambda \geq 0$. In the case that $\lim_{t \uparrow \infty} \bar{X}_t = \infty$, there should be no killing in the process (τ, H) and hence $\lambda = 0$ and we interpret $\mathbb{P}(\zeta = \infty) = 1$. Note that we may readily define the Laplace exponent of the killed process (τ, H) by

$$\mathbb{E}(e^{-\alpha\tau_t - \beta H_t} \mathbf{1}_{(t < \zeta)}) = e^{-\kappa(\alpha, \beta)t} \quad (29)$$

for all $\alpha, \beta \geq 0$ where, necessarily, $\kappa(\alpha, \beta) = \lambda + \phi(\alpha, \beta)$ is the rate of ζ , and ϕ is the bivariate Laplace exponent of the unkilld process $\{(\tau_t, H_t) : t \geq 0\}$. Analogous to the role played by joint probability generating and characteristic exponent of the pair (N, S_N) in Theorem 1 (iii), the quantity $\kappa(\alpha, \beta)$ also is prominent in the Wiener–Hopf factorization for Lévy processes, which we state below. To do so, we give one final definition. For each $t > 0$, let

$$\bar{G}_{\mathbf{e}_p} = \sup\{s < \mathbf{e}_p : X_s = \bar{X}_s\} \quad (30)$$

Theorem 2 (The Wiener–Hopf Factorization for Lévy Processes) *Suppose that X is any Lévy process other than a compound Poisson process. As usual, denote by $\mathbf{e}_p$ an independent and exponentially distributed random variable.*

(i) *The pairs*

$$(\bar{G}_{\mathbf{e}_p}, \bar{X}_{\mathbf{e}_p}) \text{ and } (\mathbf{e}_p - \bar{G}_{\mathbf{e}_p}, \bar{X}_{\mathbf{e}_p} - X_{\mathbf{e}_p}) \quad (31)$$

are independent and infinitely divisible.

(ii) *For $\alpha, \beta \geq 0$*

$$\mathbb{E} \left(e^{-\alpha \bar{G}_{\mathbf{e}_p} - \beta \bar{X}_{\mathbf{e}_p}} \right) = \frac{\kappa(p, 0)}{\kappa(p + \alpha, \beta)} \quad (32)$$

(iii) *The Laplace exponent $\kappa(\alpha, \beta)$ may be identified in terms of the law of X in the following way,*

$$\begin{aligned} \kappa(\alpha, \beta) &= k \exp \left(\int_0^\infty \int_0^\infty (e^{-t} - e^{-\alpha t - \beta x}) \right. \\ &\quad \left. \times \mathbb{P}(X_t \in dx) \frac{dt}{t} \right) \end{aligned} \quad (33)$$

where $\alpha, \beta \geq 0$ and k is a dimensionless strictly positive constant.

The First Passage Problem and Mathematical Finance

There are many applications of the Wiener–Hopf factorization in applied probability, and mathematical finance is no exception in this respect. One of the most prolific links is the relationship between the information contained in the Wiener–Hopf factorization and the distributions of the first passage times

$$\begin{aligned} \tau_x^+ &:= \inf\{t > 0 : X_t > x\} \text{ and} \\ \tau_x^- &:= \inf\{t > 0 : X_t < x\} \end{aligned} \quad (34)$$

together with the overshoots $X_{\tau_x^+} - x$ and $x - X_{\tau_x^-}$, where $x \in \mathbb{R}$. In turn, this is helpful for the pricing of certain types of exotic options.

For example, in a simple market model for which there is one risky asset modeled by an exponential Lévy process and one riskless asset with a fixed rate of return, say $r > 0$, the value of a perpetual American put, or indeed a perpetual down-and-in

put, boils down to the computation of the following quantity:

$$v_y(x) := \mathbb{E} \left(e^{-r\tau_y^-} \left(K - e^{X_{\tau_y^-}} \right)^+ | X_0 = x \right) \quad (35)$$

where $y \in \mathbb{R}$ and $z^+ = \max\{0, z\}$ and the expectation is taken with respect to an appropriate risk-neutral measure that keeps X in the class of Lévy processes (e.g., the measure that occurs as a result of the Escher transform). To see the connection with the Wiener–Hopf factorization consider the following lemma and its corollary:

Lemma 1 For all $\alpha > 0$, $\beta \geq 0$ and $x \geq 0$ we have

$$\mathbb{E} \left(e^{-\alpha\tau_x^+ - \beta X_{\tau_x^+}} \mathbf{1}_{(\tau_x^+ < \infty)} \right) = \frac{\mathbb{E} \left(e^{-\beta \bar{X}_{e_\alpha}} \mathbf{1}_{(\bar{X}_{e_\alpha} > x)} \right)}{\mathbb{E} \left(e^{-\beta \bar{X}_{e_\alpha}} \right)} \quad (36)$$

Proof First, assume that $\alpha, \beta, x > 0$ and note that

$$\begin{aligned} & \mathbb{E} \left(e^{-\beta \bar{X}_{e_\alpha}} \mathbf{1}_{(\bar{X}_{e_\alpha} > x)} \right) \\ &= \mathbb{E} \left(e^{-\beta \bar{X}_{e_\alpha}} \mathbf{1}_{(\tau_x^+ < e_\alpha)} \right) \\ &= \mathbb{E} \left(\mathbf{1}_{(\tau_x^+ < e_\alpha)} e^{-\beta X_{\tau_x^+}} \mathbb{E} \left(e^{-\beta (\bar{X}_{e_\alpha} - X_{\tau_x^+})} \middle| \mathcal{F}_{\tau_x^+} \right) \right) \end{aligned} \quad (37)$$

Now, conditionally on $\mathcal{F}_{\tau_x^+}$ and on the event $\tau_x^+ < e_\alpha$, the random variables $\bar{X}_{e_\alpha} - X_{\tau_x^+}$ and $\bar{X}_{e_\alpha}$ have the same distribution, thanks to the lack-of-memory property of e_α and the strong Markov property. Hence, we have the factorization

$$\mathbb{E} \left(e^{-\beta \bar{X}_{e_\alpha}} \mathbf{1}_{(\bar{X}_{e_\alpha} > x)} \right) = \mathbb{E} \left(e^{-\alpha\tau_x^+ - \beta X_{\tau_x^+}} \right) \mathbb{E} \left(e^{-\beta \bar{X}_{e_\alpha}} \right) \quad (38)$$

The case that β or x is equal to zero can be achieved by taking limits on both sides of the above equality.

By replacing X by $-X$ in Lemma 1, we get the following analogous result for first passage into the negative half line.

Corollary 1 For all $\alpha, \beta \geq 0$ and $x \geq 0$, we have

$$\mathbb{E} \left(e^{-\alpha\tau_{-x}^- + \beta X_{\tau_{-x}^-}} \mathbf{1}_{(\tau_{-x}^- < \infty)} \right) = \frac{\mathbb{E} \left(e^{\beta \underline{X}_{e_\alpha}} \mathbf{1}_{(-\underline{X}_{e_\alpha} > x)} \right)}{\mathbb{E} \left(e^{\beta \underline{X}_{e_\alpha}} \right)} \quad (39)$$

In that case, we may develop the expression in equation (35) by using Corollary 1 to obtain

$$v_y(x) = \frac{\mathbb{E} \left(\left(K \mathbb{E} \left[e^{\underline{X}_{e_r}} \right] - e^{x + \underline{X}_{e_r}} \right) \mathbf{1}_{(-\underline{X}_{e_r} > x - y)} \right)}{\mathbb{E} \left(e^{\underline{X}_{e_r}} \right)} \quad (40)$$

where $\underline{X}_t = \inf_{s \leq t} X_s$ is the running infimum. Ultimately, further development of the expression on the right-hand side above requires knowledge of the distribution of $\underline{X}_{e_r}$. This is information, which, in principle, can be extracted from the Wiener–Hopf factorization.

We conclude by mentioning the articles [5, 10] and [11] in which the Wiener–Hopf factorization is used for the pricing of barrier options (see **Lookback Options**).

End Notes

^aIt is this part of the proof that makes the connection with the general analytic technique of the Wiener–Hopf method of factorizing operators. This also explains the origin of the terminology *Wiener–Hopf factorization* for what is otherwise a path, and consequently distributional, decomposition.

ANDREAS E. KYPRIANOU

Poisson Process

In this article, we present the main results on Poisson processes, which are standard examples of jump processes. The reader can refer to the books [2, 5] for the study of standard Poisson processes, or [1, 3, 4, 6] for general Poisson processes.

Counting Processes and Stochastic Integrals

Let $(T_n, n \geq 0)$ be a strictly increasing sequence of random times (i.e., nonnegative random variables on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$) such that $\lim_{n \rightarrow \infty} T_n = \infty$, with $T_0 = 0$. The counting process N associated with $(T_n, n \geq 0)$ is defined as

$$N_t = \begin{cases} n & \text{if } t \in [T_n, T_{n+1}[\\ +\infty & \text{otherwise} \end{cases} \quad (1)$$

or, equivalently,

$$N_t = \sum_{n \geq 1} \mathbb{1}_{\{T_n \leq t\}} = \sum_{n \geq 1} n \mathbb{1}_{\{T_n \leq t < T_{n+1}\}} \quad (2)$$

It is an increasing, right-continuous process. We denote by N_{t-} the left limit of N_s when $s \rightarrow t, s < t$ and by $\Delta N_s = N_s - N_{s-}$ the jump process of N . The stochastic integral of a real-valued process C with respect to the increasing process N is defined as

$$\begin{aligned} (C \star N)_t &:= \int_0^t C_s dN_s = \int_{[0, t]} C_s dN_s \\ &= \sum_{n=1}^{\infty} C_{T_n} \mathbb{1}_{\{T_n \leq t\}} \end{aligned} \quad (3)$$

The natural filtration of N (i.e., the smallest right-continuous and complete filtration that makes the process N adapted) is denoted by $\mathbf{F}^N$.

Standard Poisson Process

The standard Poisson process is a counting process $(N_t, t \geq 0)$ with stationary and independent increments, that is,

- for every $s, t \geq 0$, $N_{t+s} - N_t$ is independent of $\mathcal{F}_t^N$; and

- for every $s, t \geq 0$, the r.v. $N_{t+s} - N_t$ has the same law as N_s .

For any fixed $t \geq 0$, the random variable N_t has a Poisson law, with parameter λt , that is, $\mathbb{P}(N_t = n) = e^{-\lambda t} ((\lambda t)^n / n!)$ and, for every $x > 0, t > 0, u, \alpha \in \mathbb{R}$

$$\begin{aligned} \mathbb{E}(N_t) &= \lambda t, \quad \text{Var}(N_t) = \lambda t \\ \mathbb{E}(x^{N_t}) &= e^{\lambda t(x-1)}; \quad \mathbb{E}(e^{iuN_t}) = e^{\lambda t(e^{iu}-1)}; \\ \mathbb{E}(e^{\alpha N_t}) &= e^{\lambda t(e^{\alpha}-1)} \end{aligned} \quad (4)$$

From the property of independence and stationarity of the increments, it follows that the process $(M_t := N_t - \lambda t, t \geq 0)$ is a martingale. More generally, if H is an $\mathbf{F}^N$ -predictable^a bounded process, then the following processes are $\mathbf{F}^N$ -martingales:

$$\begin{aligned} (H \star M)_t &:= \int_0^t H_s dM_s = \int_0^t H_s dN_s - \lambda \int_0^t H_s ds \\ ((H \star M)_t)^2 &- \lambda \int_0^t H_s^2 ds \\ \exp \left(\int_0^t H_s dN_s - \lambda \int_0^t (e^{H_s} - 1) ds \right) \end{aligned} \quad (5)$$

In particular, the processes $(M_t^2 - \lambda t, t \geq 0)$ and $(M_t^2 - N_t, t \geq 0)$ are martingales. The process $(\lambda t, t \geq 0)$ is the predictable quadratic variation process of M (or the compensator of N), denoted by $\langle N \rangle$, the process $(N_t, t \geq 0)$ equals in this case its optional quadratic variation, denoted by $[N]$.

The above martingale properties do not extend to $\mathbf{F}^N$ -adapted processes H . For example, from the simple equality $\int_0^t (N_s - N_{s-}) dM_s = N_t$, it follows that $\int_0^t N_s dM_s$ is not a martingale.

Predictable Representation Property

Proposition 1 *Let N be a Poisson process, and $H_\infty \in L^2(\mathcal{F}_\infty^N)$, a square-integrable random variable. Then, there exists an $\mathbf{F}^N$ -predictable process $(h_s, s \geq 0)$ such that*

$$H_\infty = \mathbb{E}(H_\infty) + \int_0^\infty h_s dM_s \quad (6)$$

and $\mathbb{E}(\int_0^\infty h_s^2 ds) < \infty$, where $M_t = N_t - \lambda t$.

It follows that if X is a square-integrable $\mathbf{F}^N$ -martingale, there exists an $\mathbf{F}^N$ -predictable process $(x_s, s \geq 0)$ such that $X_t = X_0 + \int_0^t x_s dM_s$.

Independent Poisson Processes

Here, we assume that the probability space $(\Omega, \mathcal{F}, \mathbb{P})$ is endowed with a filtration $\mathbf{F}$.

A process $(N^1, \dots, N^d)$ is a d -dimensional $\mathbf{F}$ -Poisson process (with $d \geq 1$) if each $(N^j, j = 1, \dots, d)$ is a right-continuous $\mathbf{F}$ -adapted process such that $N_0^j = 0$, and if there exist constants $(\lambda_j, j = 1, \dots, d)$ such that for every $t \geq s \geq 0$, $\forall n_j \in \mathbb{N}$,

$$\begin{aligned} \mathbb{P} \left[\bigcap_{j=1}^d (N_t^j - N_s^j = n_j) | \mathcal{F}_s \right] \\ = \prod_{j=1}^d e^{-\lambda_j(t-s)} \frac{(\lambda_j(t-s))^{n_j}}{n_j!} \end{aligned} \quad (7)$$

Proposition 2 An $\mathbf{F}$ -adapted process N is a d -dimensional $\mathbf{F}$ -Poisson process if and only if

1. each N^j is an $\mathbf{F}$ -Poisson process
2. no two N^j 's jump simultaneously.

Inhomogeneous Poisson Processes

We assume that the probability space $(\Omega, \mathcal{F}, \mathbb{P})$ is endowed with a filtration $\mathbf{F}$.

Definition

Let λ be an $\mathbf{F}$ -adapted nonnegative process satisfying $\mathbb{E} \left(\int_0^t \lambda_s ds \right) < \infty, \forall t$, and $\int_0^\infty \lambda_s ds = \infty$.

An inhomogeneous Poisson process N with stochastic intensity λ is a counting process such that for every nonnegative $\mathbf{F}$ -predictable process $(\phi_t, t \geq 0)$, the following equality is satisfied:

$$\mathbb{E} \left(\int_0^\infty \phi_s dN_s \right) = \mathbb{E} \left(\int_0^\infty \phi_s \lambda_s ds \right) \quad (8)$$

Therefore $(M_t = N_t - \int_0^t \lambda_s ds, t \geq 0)$ is an $\mathbf{F}$ -martingale, and if ϕ is an $\mathbf{F}$ -predictable process such that $\forall t, \mathbb{E}(\int_0^t |\phi_s| \lambda_s ds) < \infty$, then $(\int_0^t \phi_s dM_s, t \geq 0)$ is an $\mathbf{F}$ -martingale. The process $\Lambda_t = \int_0^t \lambda_s ds$ is called the *compensator* of N .

An inhomogeneous Poisson process with stochastic intensity λ can be viewed as a time change of $\tilde{N}$, a standard Poisson process: indeed, the process $(N_t = \tilde{N}_{\Lambda_t}, t \geq 0)$ is an inhomogeneous Poisson process with stochastic intensity $(\lambda_t, t \geq 0)$.

For H an $\mathbf{F}$ -predictable process satisfying some integrability conditions, the following processes are martingales:

$$\begin{aligned} (H \star M)_t &= \int_0^t H_s dM_s = \int_0^t H_s dN_s - \int_0^t \lambda_s H_s ds \\ ((H \star M)_t)^2 &- \int_0^t \lambda_s H_s^2 ds \\ \exp \left(\int_0^t H_s dN_s - \int_0^t \lambda_s (e^{H_s} - 1) ds \right) \end{aligned} \quad (9)$$

Stochastic Calculus

Integration by Parts Formula. Let $dX_t = b_t dt + \varphi_t dM_t$ and $dY_t = c_t dt + \psi_t dM_t$, where φ and ψ are predictable processes, and b, c are adapted processes such that the processes X and Y are well defined. Then,

$$X_t Y_t = xy + \int_0^t Y_{s-} dX_s + \int_0^t X_{s-} dY_s + [X, Y]_t \quad (10)$$

where $[X, Y]_t$ is the quadratic covariation process, defined as

$$[X, Y]_t := \int_0^t \varphi_s \psi_s dN_s \quad (11)$$

In particular, if $dX_t = \varphi_t dM_t$ and $dY_t = \psi_t dM_t$ (i.e., X and Y are local martingales), the process $(X_t Y_t - [X, Y]_t, t \geq 0)$ is a martingale. It can be noted that, in that case, the process $(X_t Y_t - \langle X, Y \rangle_t, t \geq 0)$, where $\langle X, Y \rangle_t = \int_0^t \varphi_s \psi_s \lambda_s ds$ is also a martingale. The process $\langle X, Y \rangle$ is the compensator of $[X, Y]$ if $[X, Y]$ is integrable (see **Compensators**). The predictable process $(\langle X, Y \rangle_t, t \geq 0)$ is called the *predictable covariation process* of the pair (X, Y) , or the *compensator* of the product XY . If $dX_t^i = x_t^i dN_t^i$, where $N^i, i = 1, 2$ are independent inhomogeneous Poisson processes, the covariation processes $[X^1, X^1]$ and $\langle X^1, X^2 \rangle$ are null, and $X^1 X^2$ is a martingale.

Itô's Formula. Itô's formula is a special case of the general one; it is a bit simpler and is used for the

processes that are within bounded variation. Let b be an adapted process and φ a predictable process with adequate integrability conditions, and

$$dX_t = b_t dt + \varphi_t dM_t = (b_t - \varphi_t \lambda_t) dt + \varphi_t dN_t \quad (12)$$

and $F \in C^{1,1}(\mathbb{R}^+ \times \mathbb{R})$. Then, the process $(F(t, X_t), t \geq 0)$ is a semimartingale with decomposition

$$F(t, X_t) = Z_t + A_t \quad (13)$$

where Z is a local martingale given by

$$Z_t = F(0, X_0) + \int_0^t [F(s, X_{s-} + \varphi_s) - F(s, X_{s-})] dM_s \quad (14)$$

and A a bounded variation process

$$A_t = \int_0^t (\partial_t F(s, X_s) + b_s \partial_x F(s, X_s) + \lambda_s [F(s, X_{s-} + \varphi_s) - F(s, X_s) - \varphi_s \partial_x F(s, X_s)]) ds \quad (15)$$

Exponential Martingales

Proposition 3 Let N be an inhomogeneous Poisson process with stochastic intensity $(\lambda_t, t \geq 0)$, and $(\mu_t, t \geq 0)$ a predictable process such that $\int_0^t |\mu_s| \lambda_s ds < \infty$. Then, the process L defined by

$$L_t = \begin{cases} \exp\left(-\int_0^t \mu_s \lambda_s ds\right) & \text{if } t < T_1 \\ \prod_{n, T_n \leq t} (1 + \mu_{T_n}) \times \exp\left(-\int_0^t \mu_s \lambda_s ds\right) & \text{if } t \geq T_1 \end{cases} \quad (16)$$

is a local martingale solution of

$$dL_t = L_t - \mu_t dM_t, \quad L_0 = 1 \quad (17)$$

Moreover, if μ is such that $\forall s, \mu_s > -1$,

$$\begin{aligned} L_t &= \exp\left[-\int_0^t \mu_s \lambda_s ds + \int_0^t \ln(1 + \mu_s) dN_s\right] \\ &= \exp - \int_0^t (\mu_s - \ln(1 + \mu_s)) \lambda_s ds \\ &\quad + \int_0^t \ln(1 + \mu_s) dM_s \end{aligned} \quad (18)$$

The local martingale L is denoted by $\mathcal{E}(\mu \star M)$ and named the *Doléans-Dade exponential* (alternatively, the *stochastic exponential*) of the process $\mu \star M$. If $\mu > -1$, the process L is nonnegative and is a martingale if $\forall t, \mathbb{E}(L_t) = 1$ (this is the case if μ satisfies $-1 + \delta < \mu_s < C$ where C and $\delta > 0$ are two constants).

If μ is not greater than -1 , then the process L defined in equation (16) may take negative values.

Change of Probability Measure

Let μ be a predictable process such that $\mu > -1$, and $\int_0^t \lambda_s |\mu_s| ds < \infty$, and let L be the positive exponential local martingale solution of

$$dL_t = L_t - \mu_t dM_t, \quad L_0 = 1 \quad (19)$$

Assume that L is a martingale, and let $\mathbb{Q}$ be the probability measure equivalent to $\mathbb{P}$ defined on $\mathcal{F}_t$ by $\mathbb{Q}|_{\mathcal{F}_t} = L_t \mathbb{P}|_{\mathcal{F}_t}$. Under $\mathbb{Q}$, the process

$$\begin{aligned} M_t^\mu &:= M_t - \int_0^t \mu_s \lambda_s ds \\ &= N_t - \int_0^t (\mu_s + 1) \lambda_s ds \quad t \geq 0 \end{aligned} \quad (20)$$

is a local martingale, hence N is a $\mathbb{Q}$ -inhomogeneous Poisson process, with intensity $\lambda(1 + \mu)$.

Compound Poisson Processes

Definition and Properties

Let λ be a positive number, and $F(dy)$ be a probability law on $\mathbb{R}$. A (λ, F) -compound Poisson process is a process $X = (X_t, t \geq 0)$ of the form

$$X_t = \sum_{n=1}^{N_t} Y_n = \sum_{n>0, T_n \leq t} Y_n \quad (21)$$

where N is a standard Poisson process with intensity $\lambda > 0$, and the $(Y_n, n \geq 1)$ are i.i.d. square-integrable random variables with law $F(dy) = \mathbb{P}(Y_1 \in dy)$, independent of N .

Proposition 4 A compound Poisson process has stationary and independent increments; for fixed t , the

cumulative distribution function of X_t is

$$\mathbb{P}(X_t \leq x) = e^{-\lambda t} \sum_{n=0}^{\infty} \frac{(\lambda t)^n}{n!} F^{*n}(x) \quad (22)$$

where the star indicates a convolution.

If $\mathbb{E}(|Y_1|) < \infty$, the process $(Z_t = X_t - t\lambda\mathbb{E}(Y_1), t \geq 0)$ is a martingale and $\mathbb{E}(X_t) = \lambda t\mathbb{E}(Y_1)$.

If $\mathbb{E}(Y_1^2) < \infty$, the process $(Z_t^2 - t\lambda\mathbb{E}(Y_1^2), t \geq 0)$ is a martingale and $\text{Var}(X_t) = \lambda t\mathbb{E}(Y_1^2)$.

Introducing the random measure $\mu = \sum_{n=1}^{\infty} \delta_{T_n, Y_n}$ on $\mathbb{R}^+ \times \mathbb{R}$, that is,

$$\mu(\omega,]0, t], A) = \sum_{n>0, T_n(\omega) \leq t} \mathbb{1}_{Y_n(\omega) \in A} \quad (23)$$

and denoting by $(f * \mu)_t$, the integral

$$\begin{aligned} \int_0^t \int_{\mathbb{R}} f(x) \mu(\omega, ds, dx) &= \sum_{n>0, T_n \leq t} f(Y_n(\omega)) \\ &= \sum_{n=1}^{N_t} f(Y_n(\omega)) \end{aligned} \quad (24)$$

we obtain that

$$\begin{aligned} M_t^f &= (f * \mu)_t - t\lambda\mathbb{E}(f(Y_1)) \\ &= \int_0^t \int_{\mathbb{R}} f(x) (\mu(\omega, ds, dx) - \lambda F(dx) ds) \end{aligned} \quad (25)$$

is a martingale.

Martingales

Proposition 5 *If X is a (λ, F) -compound Poisson process, for any α such that $\int_{-\infty}^{\infty} e^{\alpha x} F(dx) < \infty$, the process*

$$Z_t = \exp\left(\alpha X_t - \lambda t \int_{-\infty}^{\infty} (e^{\alpha x} - 1) F(dx)\right) \quad (26)$$

is a martingale and

$$\begin{aligned} \mathbb{E}(e^{\alpha X_t}) &= \exp\left(\lambda t \int_{-\infty}^{\infty} (e^{\alpha x} - 1) F(dx)\right) \\ &= \exp(\lambda t (\mathbb{E}(e^{\alpha Y_1}) - 1)) \end{aligned} \quad (27)$$

In other words, for any α such that $\mathbb{E}(e^{\alpha X_t}) < \infty$ (or equivalently $\mathbb{E}(e^{\alpha Y_1}) < \infty$), the process $(e^{\alpha X_t} / \mathbb{E}(e^{\alpha X_t}), t \geq 0)$ is a martingale. More generally, let f be a bounded Borel function. Then, the process

$$\exp\left(\sum_{n=1}^{N_t} f(Y_n) - \lambda t \int_{-\infty}^{\infty} (e^{f(x)} - 1) F(dx)\right) \quad (28)$$

is a martingale. In particular,

$$\begin{aligned} \mathbb{E}\left(\exp\left(\sum_{n=1}^{N_t} f(Y_n)\right)\right) \\ = \exp\left(\lambda t \int_{-\infty}^{\infty} (e^{f(x)} - 1) F(dx)\right) \end{aligned} \quad (29)$$

Change of Measure

Let X be a (λ, F) -compound Poisson process, $\tilde{\lambda} > 0$, and $\tilde{F}$ a probability measure on $\mathbb{R}$, absolutely continuous with respect to F , with Radon–Nikodym density φ , that is, $\tilde{F}(dx) = \varphi(x)F(dx)$. The process

$$L_t = \exp\left(t(\lambda - \tilde{\lambda}) + \sum_{s \leq t} \ln\left(\frac{\tilde{\lambda}}{\lambda} \varphi(\Delta X_s)\right)\right) \quad (30)$$

is a positive martingale (take $f(x) = \ln((\tilde{\lambda}/\lambda) \varphi(x))$ in equation (28)) with expectation 1. Set $d\mathbb{Q}|_{\mathcal{F}_t} = L_t d\mathbb{P}|_{\mathcal{F}_t}$.

Proposition 6 *Under $\mathbb{Q}$, the process X is a $(\tilde{\lambda}, \tilde{F})$ -compound Poisson process.*

Let α be such that $\mathbb{E}(e^{\alpha Y_1}) < \infty$. The particular case with $\varphi(x) = (e^{\alpha x} / \mathbb{E}(e^{\alpha Y_1}))$ and $\tilde{\lambda} = \lambda \mathbb{E}(e^{\alpha Y_1})$ corresponds to the Esscher transform for which

$$d\mathbb{Q}|_{\mathcal{F}_t} = \frac{e^{\alpha X_t}}{\mathbb{E}(e^{\alpha X_t})} d\mathbb{P}|_{\mathcal{F}_t} \quad (31)$$

We emphasize that there exist changes of probability that do not preserve the compound Poisson process property. For the predictable representation theorem, see **Point Processes**.

An Example: Double Exponential Model

The compound Poisson process is said to be a double exponential process if the law of the random variable Y_1 is

$$F(dx) = \left(p\theta_1 e^{-\theta_1 x} \mathbb{1}_{\{x>0\}} + (1-p)\theta_2 e^{\theta_2 x} \mathbb{1}_{\{x<0\}} \right) dx \quad (32)$$

where $p \in]0, 1[$ and $\theta_i, i = 1, 2$ are positive numbers. Under an Esscher transform, this model is still a double exponential model. This particular dynamic allows one to compute the Laplace transform of the first hitting times of a given level.

End Notes

^aWe recall that adapted continuous-on-left processes are predictable. The process N is not predictable.

Point Processes

This article gives a brief overview of general point processes. We refer to the books [1–5], for proofs and advanced results.

Marked Point Processes

Definition

An increasing sequence of random times is called a *univariate point process*. A simple example is the Poisson process.

Given a univariate point process, we associate to every time T_n a mark Z_n . More precisely, let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, $(Z_n, n \geq 1)$ a sequence of random variables taking values in a measurable space $(E, \mathcal{E})$, and $(T_n, n \geq 1)$ an increasing sequence of nonnegative random variables. We assume that $\lim T_n = \infty$, so that there is only a finite number of n such that, for a given t , one has $T_n \leq t$. We define the process $\mathbf{N}$ as follows. For each set, $A \in \mathcal{E}$, $N_t(A) = \sum_n \mathbb{1}_{\{T_n \leq t\}} \mathbb{1}_{\{Z_n \in A\}}$ is the number of “marks” in the set A before time t . The natural filtration of $\mathbf{N}$ is

$$\mathcal{F}_t^{\mathbf{N}} = \sigma(N_s(A), s \leq t, A \in \mathcal{E}) \quad (1)$$

The predictable σ -algebra $\mathcal{P}$ is the σ -algebra defined on $\Omega \times \mathbb{R}^+$ that is generated by the sets

$$A \times \{0\}, A \in \mathcal{F}_0^{\mathbf{N}}; \quad A \times]s, t], A \in \mathcal{F}_s^{\mathbf{N}}, s \leq t \quad (2)$$

The associated random counting measure $\mu(\omega, ds, dz)$ is defined as follows: let Φ be a map

$$(t, \omega, z) \in (\mathbb{R}^+, \Omega, E) \rightarrow \Phi(t, \omega, z) \in \mathbb{R} \quad (3)$$

We set

$$\begin{aligned} \int_{[0,t]} \int_E \Phi(s, z) \mu(ds, dz) &= \sum_{n=1}^{\infty} \Phi(T_n, Z_n) \mathbb{1}_{\{T_n \leq t\}} \\ &= \sum_{n=1}^{N_t(E)} \Phi(T_n, Z_n) \end{aligned} \quad (4)$$

The process $\mathbf{N}$ is called a *marked point process*. This is a generalization of the compound Poisson process: we have introduced, in particular, a spatial dimension for the size of jumps, which are no more i.i.d. random variables.

A map Φ is predictable if it is $\mathcal{P} \otimes \mathcal{E}$ measurable. The *compensator* of the marked point process $\mathbf{N}$ is the unique predictable random measure ν on $(\mathbb{R}^+ \times E, \mathcal{G} \otimes \mathcal{E})$ such that, for every bounded predictable process Φ

$$\begin{aligned} \mathbb{E} \left(\int_0^t \int_E \Phi(s, z; \omega) \mu(\omega; ds, dz) \right) \\ = \mathbb{E} \left(\int_0^t \int_E \Phi(s, z; \omega) \nu(\omega; ds, dz) \right) \end{aligned} \quad (5)$$

In the case of a marked point process on $\mathbb{R} \times \mathbb{R}^d$, the compensator admits an explicit representation: let $G_n(dt, dz)$ be a regular version of the conditional distribution of (T_{n+1}, Z_{n+1}) with respect to $\mathcal{F}_{T_n}^{\mathbf{N}} = \sigma\{(T_1, Z_1), \dots, (T_n, Z_n)\}$. Then,

$$\nu(dt, dz) = \sum_n \mathbb{1}_{\{T_n < t \leq T_{n+1}\}} \frac{G_n(dt, dz)}{G_n([t, \infty[\times \mathbb{R}^d)} \quad (6)$$

Intensity Process

In what follows, we assume that, for any $A \in \mathcal{E}$, the process $(N_t(A), t \geq 0)$ admits the $\mathbf{F}$ -predictable intensity $(\lambda_t(A), t \geq 0)$, that is, there exists a non-negative process $(\lambda_t(A), t \geq 0)$ such that

$$N_t(A) - \int_0^t \lambda_s(A) ds \quad (7)$$

is an $\mathbf{F}$ -martingale. Then, if $X_t = \sum_{n=1}^{N_t(E)} \Phi(T_n, Z_n)$ where Φ is an $\mathbf{F}$ -predictable process that satisfies

$$\mathbb{E} \left(\int_{[0,t]} \int_E |\Phi(s, z)| \lambda_s(dz) ds \right) < \infty \quad (8)$$

the process

$$\begin{aligned} X_t - \int_0^t \int_E \Phi(s, z) \lambda_s(dz) ds \\ = \int_{[0,t]} \int_E \Phi(s, z) [\mu(ds, dz) - \lambda_s(dz) ds] \end{aligned} \quad (9)$$

is a martingale and, in particular,

$$\begin{aligned} \mathbb{E} \left(\int_{[0,t]} \int_E \Phi(s, z) \mu(ds, dz) \right) \\ = \mathbb{E} \left(\int_{[0,t]} \int_E \Phi(s, z) \lambda_s(dz) ds \right) \end{aligned} \quad (10)$$

The random measure $\mu(ds, dz) - \lambda_s(dz)ds$ is the compensated measure of μ .

Example Compound Poisson Process. Let $X_t = \sum_{n=1}^{N_t} Y_n$ be a (λ, F) -compound Poisson process. We can consider the Y_n s as marks and introduce the marked point process $N_t(A) = \sum_{n=1}^{N_t} \mathbb{1}_{Y_n \in A}$. For any A , the process $(N_t(A), t \geq 0)$ is a compound Poisson process, and $(N_t(A) - \lambda t P(Y_1 \in A), t \geq 0)$ is a martingale. The intensity of the marked point process $\mathbf{N}$ is $\lambda_t(dz) = \lambda F(dz)$. Moreover, if A_i are disjoint sets, the processes $N(A_i)$ are independent. The counting random measure μ satisfies

$$\int_0^t \int_{\mathbb{R}} f(x) \mu(\omega; ds, dx) = \sum_{k=1}^{N_t} f(Y_k) \quad (11)$$

and we obtain, in particular, that, as in the article on Poisson processes (see **Poisson Process**)

$$M_t^f = \int_0^t \int_{\mathbb{R}} f(x) (\mu(\omega; ds, dx) - ds \lambda F(dx)) \quad (12)$$

is a martingale.

Predictable Representation Property

Let $\mathbf{F}^{\mathbf{N}}$ be the filtration generated by the marked point process with intensity $\lambda_s(dz)$. Then, any $(\mathbb{P}, \mathbf{F}^{\mathbf{N}})$ -martingale M admits the representation

$$M_t = M_0 + \int_0^t \int_E \Phi(s, x) (\mu(ds, dx) - \lambda_s(dx)ds) \quad (13)$$

where Φ is a $\mathbf{F}^{\mathbf{N}}$ -predictable process such that

$$\mathbb{E} \left(\int_0^t \int_E |\Phi(s, x)| \lambda_s(dx) ds \right) < \infty \quad (14)$$

Change of Probability Measure

Let μ be the random measure of a marked point process with intensity $\lambda_t(A) = \alpha_t m_t(A)$, where m is a probability measure. We shall say that the marked point process admits $(\alpha_t, m_t(dz))$ as P -local characteristics. Let $(\psi_t, h_t(z))$ be two predictable positive processes such that

$$\int_0^t \psi_s \alpha_s ds < \infty, \quad \int_E h_s(z) m_t(dz) = 1 \quad (15)$$

Let L be the solution of

$$\begin{aligned} dL_t = L_{t-} \int_E (\psi_t h_t(z) - 1) (\mu(dt, dz) \\ - \alpha_t m_t(dz) dt), \quad L_0 = 1 \end{aligned} \quad (16)$$

If $\mathbb{E}(L_t) = 1$ (so that L is a martingale), setting $\mathbb{Q}|_{\mathcal{F}_t} = L_t \mathbb{P}|_{\mathcal{F}_t}$, the marked point process has the $\mathbb{Q}$ -local characteristics $(\psi_t \alpha_t, h_t(z) m_t(dz))$.

Example Compound Poisson Process. The change of measure for compound Poisson processes can be written in terms of random measures. Let

$$\begin{aligned} L_t = \exp \left(\int_{\mathbb{R}} f(x) N_t(dx) \right. \\ \left. - t \lambda \int_{-\infty}^{\infty} (e^{f(x)} - 1) F(dx) \right) \\ = \exp \left(\int_0^t \int_{\mathbb{R}} f(x) \mu(ds, dx) \right. \\ \left. - t \int_{-\infty}^{\infty} (e^{f(x)} - 1) \lambda F(dx) \right) \end{aligned} \quad (17)$$

be a martingale. Define $d\mathbb{Q}|_{\mathcal{F}_t} = L_t d\mathbb{P}|_{\mathcal{F}_t}$. Then,

$$\int_0^t \int_{\mathbb{R}} (\mu(ds, dx) - ds e^{f(x)} \lambda F(dx)) \quad (18)$$

is a $\mathbb{Q}$ -martingale as obtained in the article on Poisson processes (see **Poisson Process**).

Poisson Point Processes

Poisson Measures

Let $(E, \mathcal{E})$ be a measurable space. A random measure μ on $(E, \mathcal{E})$ is a Poisson measure with intensity ν , where ν is a σ -finite measure on $(E, \mathcal{E})$, if

1. for every set $B \in \mathcal{E}$ with $\nu(B) < \infty$, $\mu(B)$ follows a Poisson distribution with parameter $\nu(B)$;
2. for disjoint sets $B_i, i \leq n$, the variables $\mu(B_i), i \leq n$ are independent.

Point Processes

Let $(E, \mathcal{E})$ be a measurable space and δ an additional point. We set $E_\delta = E \cup \delta$, $\mathcal{E}_\delta = \sigma(\mathcal{E}, \{\delta\})$.

Definition 1 Let $\mathbf{e}$ be a stochastic process defined on a probability space $(\Omega, \mathcal{F}, P)$, taking values in $(E_\delta, \mathcal{E}_\delta)$. The process $\mathbf{e}$ is a point process if

1. the map $(t, \omega) \rightarrow \mathbf{e}_t(\omega)$ is $\mathcal{B}([0, \infty[) \otimes \mathcal{F}$ -measurable;
2. the set $D_\omega = \{t : \mathbf{e}_t(\omega) \neq \delta\}$ is a.s. countable.

For every measurable set B of $]0, \infty[\times E$, we set

$$N^B(\omega) := \sum_{s \geq 0} \mathbb{1}_B(s, \mathbf{e}_s(\omega)) \quad (19)$$

In particular, if $B =]0, t] \times \Gamma$, we write

$$N_t^\Gamma = N^B = \text{Card}\{s \leq t : \mathbf{e}(s) \in \Gamma\} \quad (20)$$

Poisson Point Processes

Definition 2 An $\mathbf{F}$ -Poisson point process $\mathbf{e}$ is a point process such that

1. $N_t^E < \infty$ a.s. for every t
2. for any $\Gamma \in \mathcal{E}$, the process N^Γ is $\mathbf{F}$ -adapted
3. for any s and t and any $\Gamma \in \mathcal{E}$, $N_{s+t}^\Gamma - N_t^\Gamma$ is independent from $\mathcal{F}_t$ and distributed as N_s^Γ .

In particular, for any disjoint family $(\Gamma_i, i = 1, \dots, d)$, the d -dimensional process $(N_t^{\Gamma_i}, i = 1, \dots, d)$ is a Poisson process.

Definition 3 The σ -finite measure on $\mathcal{E}$ defined by

$$\mathbf{n}(\Gamma) = \frac{1}{t} \mathbb{E}(N_t^\Gamma) \quad (21)$$

is called the characteristic measure of $\mathbf{e}$.

If $\mathbf{n}(\Gamma) < \infty$, the process $N_t^\Gamma - t\mathbf{n}(\Gamma)$ is an $\mathbf{F}$ -martingale.

Proposition 1 (Compensation Formula).

Let H be a measurable positive process vanishing at δ . Then

$$\begin{aligned} & \mathbb{E} \left[\sum_{s \geq 0} H(s, \omega, \mathbf{e}_s(\omega)) \right] \\ &= \mathbb{E} \left[\int_0^\infty ds \int H(s, \omega, u) \mathbf{n}(du) \right] \end{aligned} \quad (22)$$

If, for any t , $\mathbb{E} \left[\int_0^t ds \int H(s, \omega, u) \mathbf{n}(du) \right] < \infty$, the process

$$\sum_{s \leq t} H(s, \omega, \mathbf{e}_s(\omega)) - \int_0^t ds \int H(s, \omega, u) \mathbf{n}(du) \quad (23)$$

is a martingale.

Proposition 2 (Exponential Formula).

If f is a measurable function such that $\int_0^t ds \int |f(s, u)| \mathbf{n}(du) < \infty$ for every t , then,

$$\begin{aligned} & \mathbb{E} \left[\exp \left(i \sum_{0 < s \leq t} f(s, \mathbf{e}_s) \right) \right] \\ &= \exp \left(\int_0^t ds \int (e^{if(s, u)} - 1) \mathbf{n}(du) \right) \end{aligned} \quad (24)$$

Moreover, if $f \geq 0$,

$$\begin{aligned} & \mathbb{E} \left[\exp \left(- \sum_{0 < s \leq t} f(s, \mathbf{e}_s) \right) \right] \\ &= \exp \left(- \int_0^t ds \int (1 - e^{-f(s, u)}) \mathbf{n}(du) \right) \end{aligned} \quad (25)$$

MONIQUE JEANBLANC

Compensators

In probability theory, the *compensator* of a stochastic process designates a quantity that, once subtracted from a stochastic process, yields a martingale.

Compensator of a Random Time

Let $(\Omega, \mathbf{G}, \mathbb{P})$ be a filtered probability space and τ a $\mathbf{G}$ -stopping time. The process $H_t = \mathbb{1}_{\tau \leq t}$ is a $\mathbf{G}$ -adapted increasing process, hence a $\mathbf{G}$ -submartingale and admits a Doob–Meyer decomposition as

$$H_t = M_t + \Lambda_t \quad (1)$$

where M is a $\mathbf{G}$ -local martingale and Λ a $\mathbf{G}$ -predictable increasing process. The process Λ , called the *$\mathbf{G}$ -compensator* of H , is constant after τ , that is, $\Lambda_t = \Lambda_{t \wedge \tau}$. The process Λ “compensates” H with the meaning that $H - \Lambda$ is a martingale. If τ is $\mathbf{G}$ -predictable, then $\Lambda_t = H_t$. The continuity of Λ is equivalent to the fact that τ is a $\mathbf{G}$ -totally inaccessible stopping time. If Λ is absolutely continuous with respect to the Lebesgue measure, that is, if $\Lambda_t = \int_0^t \lambda_s^{\mathbf{G}} ds$, the nonnegative $\mathbf{G}$ -adapted process $\lambda^{\mathbf{G}}$ is called the *intensity rate* of τ . Note that $\lambda_t^{\mathbf{G}}$ is null on the set $\tau \leq t$.

For any integrable random variable $X \in \mathcal{G}_T$, one has

$$\mathbb{E}(X \mathbb{1}_{T < \tau} | \mathcal{G}_t) = \mathbb{1}_{\{t < \tau\}} (V_t - \mathbb{E}(\Delta V_\tau \mathbb{1}_{\tau \leq T} | \mathcal{G}_t)) \quad (2)$$

with $V_t = e^{\Lambda_t} \mathbb{E}(X e^{-\Lambda_\tau} | \mathcal{G}_t)$.

In the following examples, τ is a given random time, that is, a nonnegative random variable, and $\mathbf{H}$ the natural filtration of H (i.e., the smallest filtration satisfying the usual conditions such that the process H is adapted). The random time τ is a $\mathbf{H}$ -stopping time.

Elementary Case

Let τ be an exponential random variable with constant parameter λ . Then, the $\mathbf{H}$ -compensator of H is $\lambda(t \wedge \tau)$. More generally, if τ is a nonnegative random variable with cumulative distribution function F , taken continuous on the right ($F(t) = \mathbb{P}(\tau \leq t)$) such

that $\forall t, F(t) < 1$, the $\mathbf{H}$ -compensator of τ is $\Lambda_t = \int_0^{t \wedge \tau} \frac{dF(s)}{1-F(s-)}$. If F is continuous, the $\mathbf{H}$ -compensator is $\Lambda_t = -\ln(1 - F(t \wedge \tau))$.

Cox Processes

Let $\mathbf{F}$ be a given filtration, λ a given $\mathbf{F}$ -adapted nonnegative process, $\Lambda_t^{\mathbf{F}} = \int_0^t \lambda_s ds$, and Θ a random variable with exponential law, independent of $\mathbf{F}$. Let us define the random time τ as

$$\tau = \inf \{t : \Lambda_t^{\mathbf{F}} \geq \Theta\} \quad (3)$$

Then, the process

$$\mathbb{1}_{\tau \leq t} - \int_0^{t \wedge \tau} \lambda_s ds = \mathbb{1}_{\tau \leq t} - \Lambda_{t \wedge \tau}^{\mathbf{F}} \quad (4)$$

is a martingale in the filtration $\mathbf{G} = \mathbf{F} \vee \mathbf{H}$, the smallest filtration that contains $\mathbf{F}$, making τ a stopping time (in fact a totally inaccessible stopping time). The $\mathbf{G}$ -compensator of H is $\Lambda_t = \Lambda_{t \wedge \tau}^{\mathbf{F}}$, and the $\mathbf{G}$ -intensity rate is $\lambda_t^{\mathbf{G}} = \mathbb{1}_{t < \tau} \lambda_t$. In that case, for an integrable random variable $X \in \mathcal{F}_T$, one has

$$\mathbb{E}(X \mathbb{1}_{T < \tau} | \mathcal{G}_t) = \mathbb{1}_{t < \tau} e^{\Lambda_t^{\mathbf{F}}} \mathbb{E}(X e^{-\Lambda_t^{\mathbf{F}}} | \mathcal{F}_t) \quad (5)$$

and, for H , an $\mathbf{F}$ -predictable (bounded) process

$$\begin{aligned} \mathbb{E}(H_\tau \mathbb{1}_{\tau \leq T} | \mathcal{G}_t) &= H_\tau \mathbb{1}_{\tau \leq t} \\ &+ \mathbb{1}_{t < \tau} e^{\Lambda_t^{\mathbf{F}}} \mathbb{E} \left(\int_t^T H_s e^{-\Lambda_s^{\mathbf{F}}} \lambda_s ds | \mathcal{F}_t \right) \end{aligned} \quad (6)$$

Conditional Survival Probability

Assume now that τ is a nonnegative random variable on the filtered probability space $(\Omega, \mathbf{F}, \mathbb{P})$ with conditional survival probability $G_t := \mathbb{P}(\tau > t | \mathcal{F}_t)$, taken continuous on the right and let $\mathbf{G} = \mathbf{F} \vee \mathbf{H}$. The random time τ is a $\mathbf{G}$ -stopping time.

If τ is an $\mathbf{F}$ -predictable stopping time (hence a $\mathbf{G}$ -predictable stopping time), then $G_t = \mathbb{1}_{\tau > t}$ and $\Lambda = H$.

In what follows, we assume that $G_t > 0$ and we introduce the Doob–Meyer decomposition of the $\mathbf{F}$ -supermartingale G , that is, $G_t = Z_t - A_t$, where Z is an $\mathbf{F}$ -martingale and A is an increasing $\mathbf{F}$ -predictable process. Then, the $\mathbf{G}$ -compensator of τ is $\Lambda_t = \int_0^{t \wedge \tau} (G_{s-})^{-1} dA_s$. If $dA_t = a_t dt$, the $\mathbf{G}$ -intensity rate is $\lambda_t^{\mathbf{G}} = \mathbb{1}_{t < \tau} (G_{t-})^{-1} a_t$. Moreover, if G

is continuous, then for an integrable random variable $X \in \mathcal{F}_T$, one has

$$\mathbb{E}(X \mathbb{1}_{T < \tau} | \mathcal{G}_t) = \mathbb{1}_{t < \tau} (G_t)^{-1} \mathbb{E}(X G_T | \mathcal{F}_t) \quad (7)$$

It is often convenient to introduce the $\mathbf{F}$ -adapted process $\tilde{\lambda}_t = (G_t)^{-1} a_t$, equal to $\lambda_t^{\mathbf{G}}$ on the set $t < \tau$. We shall call this process the *predefault-intensity* process.

A particular case occurs when the process G is nonincreasing and absolutely continuous with respect to the Lebesgue measure, that is, $G_t = \int_t^\infty g_s ds$, where $g \geq 0$. In that case, the $\mathbf{G}$ -adapted intensity rate is $\lambda_t^{\mathbf{G}} = (G_t)^{-1} g_t \mathbb{1}_{t < \tau}$, the predefault intensity is $\tilde{\lambda}_t = (G_t)^{-1} g_t$ and, for an integrable random variable $X \in \mathcal{F}_T$,

$$\mathbb{E}(X \mathbb{1}_{T < \tau} | \mathcal{G}_t) = \mathbb{1}_{t < \tau} e^{\Lambda_t^{\mathbf{F}}} \mathbb{E}(X e^{-\Lambda_t^{\mathbf{F}}} | \mathcal{F}_t) \quad (8)$$

where $\Lambda^{\mathbf{F}}$ is the $\mathbf{F}$ -adapted process defined as

$$\Lambda_t^{\mathbf{F}} = \int_0^t \tilde{\lambda}_s ds = \int_0^t (G_s)^{-1} g_s ds \quad (9)$$

Aven's Lemma

The Aven lemma has the following form: let $(\Omega, \mathcal{G}_t, \mathbb{P})$ be a filtered probability space and N be a counting process. Assume that $E(N_t) < \infty$ for any t . Let $(h_n, n \geq 1)$ be a sequence of real numbers converging to 0, and

$$Y_t^{(n)} = \frac{1}{h_n} E(N_{t+h_n} - N_t | \mathcal{G}_t) \quad (10)$$

Assume that there exists λ_t and y_t nonnegative $\mathbb{G}$ -adapted processes such that

1. For any t , $\lim Y_t^{(n)} = \lambda_t$ (11)
2. For any t , there exists for almost all ω an $n_0 = n_0(t, \omega)$ such that

$$|Y_s^{(n)} - \lambda_s(\omega)| \leq y_s(\omega), \quad s \leq t, \quad n \geq n_0(t, \omega) \quad (12)$$

3. $\int_0^t y_s ds < \infty, \forall t$ (13)

Then, $N_t - \int_0^t \lambda_s ds$ is a $\mathbb{G}$ -martingale.

For the particular case of a random time, we obtain the following: assume that $\lim_{h \rightarrow 0} \frac{1}{h} \mathbb{P}(t < \tau \leq t +$

$h | \mathcal{G}_t) = \lambda_t^{\mathbf{G}}$, and that, there exists a Lebesgue integrable process y such that $|\frac{1}{h} \mathbb{P}(t < \tau \leq t + h | \mathcal{G}_t) - \lambda_t^{\mathbf{G}}| \leq y_t$ for any h small enough. Then $\lambda^{\mathbf{G}}$ is the $\mathbf{G}$ -intensity of τ .

In the case of conditional survival probability model, the predefault intensity $\tilde{\lambda}^{\mathbf{G}}$ is

$$\tilde{\lambda}_t^{\mathbf{G}} = \lim_{h \rightarrow 0} \frac{1}{h \mathbb{P}(t < \tau | \mathcal{F}_t)} \mathbb{P}(t < \tau \leq t + h | \mathcal{F}_t) \quad (14)$$

See [2] for an extensive study.

Shrinking

Assume that $\mathbf{G}^*$ is a subfiltration of $\mathbf{G}$ such that τ is a $\mathbf{G}^*$ (and a $\mathbf{G}$) stopping time. Assume that τ admits a $\mathbf{G}$ -intensity rate equal to $\lambda^{\mathbf{G}}$. Then, the $\mathbf{G}^*$ -intensity of τ is $\lambda_t^* = \mathbb{E}(\lambda_t^{\mathbf{G}} | \mathcal{F}_t^*)$ (see [1]).

As we have seen above, in the survival probability approach, the value of the intensity can be given in terms of the conditional survival probability. Assume that $G_t = \mathbb{P}(\tau > t | \mathcal{F}_t) = Z_t - \int_0^t a_s ds$, where Z is an $\mathbf{F}$ -martingale and that $\mathbf{G}^* = \mathbf{F}^* \vee \mathbf{H}$ where, $\mathbf{F}^* \subset \mathbf{F}$. Then, the $\mathbf{F}^*$ -conditional survival probability of τ is

$$G_t^* = \mathbb{P}(\tau > t | \mathcal{F}_t^*) = \mathbb{E}(G_t | \mathcal{F}_t^*) = X_t^* - \int_0^t a_s^* ds \quad (15)$$

where X^* is an $\mathbf{F}^*$ -martingale and $a_s^* = \mathbb{E}(a_s | \mathcal{F}_s^*)$. It follows that the $\mathbf{G}^*$ -intensity rate of τ writes as (we assume, for simplicity, that G and G^* are continuous)

$$\lambda_t^* = \mathbb{1}_{t < \tau} \frac{a_t^*}{G_t^*} = \mathbb{1}_{t < \tau} \frac{\mathbb{E}(\lambda_t^{\mathbf{G}} G_t | \mathcal{F}_t^*)}{\mathbb{E}(G_t | \mathcal{F}_t^*)} \quad (16)$$

It is useful to note that one can start with a model in which τ is an $\mathbf{F}$ -predictable stopping time (hence $\mathbf{G} = \mathbf{F}$, and a $\mathbf{G}$ -intensity rate does not exist) and consider a smaller filtration (e.g., the trivial filtration) for which there exists an intensity rate, computed by means of the conditional survival probability.

Compensator of an Increasing Process

The notion of interest in this section is that of *dual predictable projection*, which we define as follows:

Proposition 1 *Let A be an integrable increasing process (not necessarily $\mathbf{F}$ -adapted). There*

exists a unique $\mathbf{F}$ -predictable increasing process $(A_t^{(p)}, t \geq 0)$, called the $\mathbf{F}$ -dual predictable projection of A such that

$$\mathbb{E} \left(\int_0^\infty H_s dA_s \right) = \mathbb{E} \left(\int_0^\infty H_s dA_s^{(p)} \right) \quad (17)$$

for any positive $\mathbf{F}$ -predictable process H .

The definition of compensator of a random time can be interpreted in terms of dual predictable projection: if τ is a random time, the F -predictable compensator associated with τ is the dual predictable projection A^τ of the increasing process $\mathbb{1}_{\{\tau \leq t\}}$. It satisfies

$$\mathbb{E}(k_\tau) = \mathbb{E} \left(\int_0^\infty k_s dA_s^\tau \right) \quad (18)$$

for any positive, $\mathbf{F}$ -predictable process k .

Examples

Covariation Processes. Let M be a martingale and $[M]$ its quadratic variation process. If $[M]$ is integrable, its compensator is $\langle M \rangle$.

Standard Poisson Process. If N is a Poisson process, $(M_t = N_t - \lambda t, t \geq 0)$ is a martingale, and λt is the compensator of N ; the martingale M is called the *compensated martingale*.

Compensated Poisson Integrals. Let N be a time inhomogeneous Poisson process with deterministic intensity λ and $\mathbf{F}^N$ its natural filtration. The process

$$\left(M_t = N_t - \int_0^t \lambda(s) ds, t \geq 0 \right) \quad (19)$$

is an $\mathbf{F}^N$ -martingale. The increasing function $\Lambda(t) := \int_0^t \lambda(s) ds$ is called the (deterministic) *compensator* of N .

Random Measures

Definitions

The *compensator* of a random measure μ is the unique random measure ν such that

1. for every predictable process H , the process $(H \star \nu)$ is predictable (the measure ν is said to be predictable) and
2. for every predictable process H such that the process $|H| \star \mu$ is increasing and locally integrable, the process $(H \star \mu - H \star \nu)$ is a local martingale.

Examples

If N is a Lévy process with Lévy measure ν

$$\begin{aligned} & \int_{\Lambda} f(x) N_t(\cdot, dx) - t \int_{\Lambda} f(x) \nu(dx) \\ &= \sum_{0 < s \leq t} (f(\Delta X_s) \mathbb{1}_{\Lambda}(\Delta X_s)) - t \int_{\Lambda} f(x) \nu(dx) \end{aligned} \quad (20)$$

is a martingale, the compensator of $\int_{\Lambda} f(x) N_t(\cdot, dx)$ is $t \int_{\Lambda} f(x) \nu(dx)$.

For other examples see the article on point processes (see **Point Processes**).

Heavy Tails

The three most cited stylized properties attributed to log-returns of financial assets or stocks are (i) a kurtosis much larger than 3, the kurtosis of a normal distribution; (ii) serial dependence without correlation; and (iii) volatility clustering. Any realistic and useful model for log-returns must account for all three of these characteristics. In this article, the focus is on the large kurtosis property, which is indicative of heavy tails in the returns. Although this stylized fact may not draw the same level of attention as the other two, it can have a serious impact on modeling and inference questions related to financial time series. One such application is the estimation of the Value at Risk, which is an important entity in the finance industry. For example, financial institutions would like to estimate large quantiles of the absolute returns, that is, the level at which the probability that an absolute return exceeds this value is small such as 0.01 or less. The estimation of these large quantities is extremely sensitive to the shape assumed for the tail of the marginal distribution. A light-tailed assumption for the tails can severely underestimate the actual quantiles of the marginal distribution. In addition to Value at Risk, heavy tails can impact the estimation of key measures of dependencies in financial time series. This includes the sample autocorrelation of the time series and of functions of the time series such as absolute values and squares. Standard central limit theory for mixing sequences generally directly applies to the sample autocorrelation functions (ACFs) of a financial time series and its squares, provided the fourth and eight moments, respectively, are finite. If these moments are infinite, as well may be the case for financial time series, then the asymptotic behavior of the sample ACFs is often nonstandard. As it turns out, GARCH processes and stochastic volatility (SV) processes, which are the primary modeling engines for financial returns, exhibit heavy tails in the marginal distribution. We focus on heavy tails and how the concept of regular variation plays a vital role in both these processes.

It is often a misconception to associate heavy-tailed distributions with a very large variance. Rather, the term is used to describe data that exhibit bursts of outlying observations. These outlying observations could be orders of magnitude larger than the median

of the observations. In the early 1960s, Mandelbrot (see **Mandelbrot, Benoit**) [31], Mandelbrot and Taylor [32], and Fama [21] realized that the marginal distribution of returns appeared to be heavy tailed. To cope with heavy tails, they considered non-Gaussian stable distributions for the marginals. Since this class of distributions has infinite variance, it was a slightly controversial approach. On the other hand, for many financial time series, there is evidence that the marginal distribution may have a finite variance but an infinite fourth moment. Figure 1 contains two financial time series that exhibit heavy tails. Figure 1(a) consists of the daily pound/US dollar exchange rate from October 1, 1981 to June 28, 1985, while Figure 1(b) displays the log-returns of the daily closing price of Merck stock from January 2, 2003 through April 28, 2006. One can certainly detect the occasional bursts of outlying observations in both series that are representative of heavy tails. As described in the second section (see Figure 3c and d), there is statistical evidence that the tail behavior of the marginal distribution is heavy with possibly infinite fourth moments.

Regular variation is a natural and often used concept to describe and model heavy-tailed phenomena. Many processes that are designed to model financial time series, such as the GARCH and heavy-tailed SV processes, have the property that all finite-dimensional distributions are regularly varying. For such processes, one can apply standard results from extreme value theory for establishing limiting behavior of the extremes of the process, the sample ACF of the process and its squares, and a host of other statistics. The regular variation condition and its properties are described in the second section. In the third section, some of the main results on regular variation for GARCH and SV processes, respectively, are described. The fourth section describes some of the applications of the regular variation conditions mentioned in the third section, with emphasis on extreme values, point processes, and sample autocorrelations.

Regular Variation

Multivariate regular variation plays an indispensable role in extreme value theory and often serves as the starting point for modeling multivariate extremes. In some respect, one can regard a random vector that is regularly varying as the heavy-tailed analog

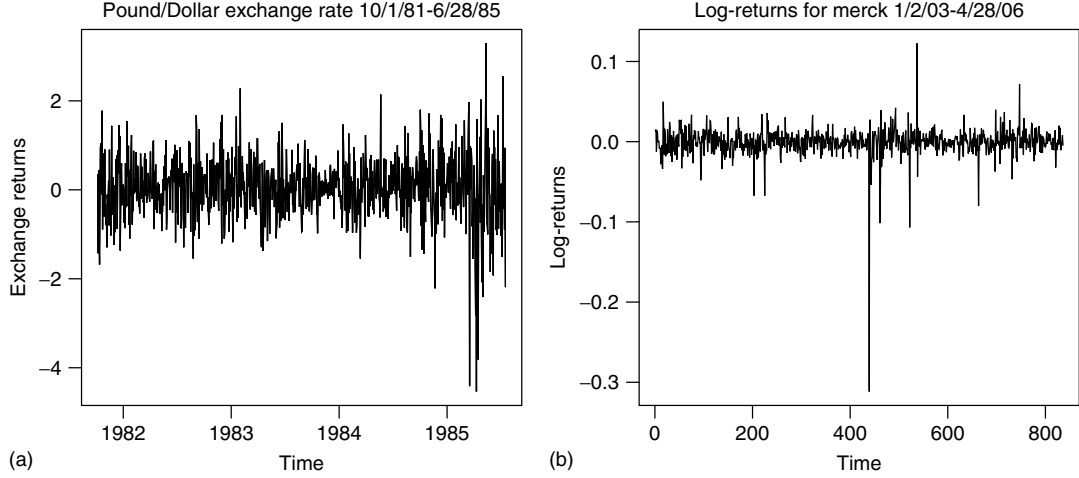

Figure 1 Log-returns for US/pound exchange rate, October 1, 1981 to June 28, 1985 (a) and log-returns for closing price of Merck stock, January 2, 2003 to April 28, 2006 (b)

of a Gaussian random vector. Unlike a Gaussian random vector, which is characterized by the mean vector and all pairwise covariances, a regular varying random vector in d dimensions is characterized by two components, an index $\alpha > 0$ and a random vector Θ with values in $\mathbb{S}^{d-1}$, where $\mathbb{S}^{d-1}$ denotes the unit sphere in $\mathbb{R}^d$ with respect to the norm $|\cdot|$. The random vector $\mathbf{X}$ is said to be *regularly varying* with index $-\alpha$ if for all $t > 0$,

$$\frac{P(|\mathbf{X}| > tu, \mathbf{X}/|\mathbf{X}| \in \cdot)}{P(|\mathbf{X}| > u)} \xrightarrow{v} t^{-\alpha} P(\Theta \in \cdot) \quad (1)$$

as $u \rightarrow \infty$

The symbol $\xrightarrow{v}$ stands for vague convergence on $\mathbb{S}^{d-1}$; vague convergence of measures is treated in detail in [27]. See [24, 36, 37] for background on multivariate regular variation. In this context, the convergence in equation (1) holds for all continuity sets $A \in \mathcal{B}(\mathbb{S}^{d-1})$ of Θ . In particular, equation (1) implies that the modulus of the random vector $|\mathbf{X}|$ is regularly varying, that is,

$$\lim_{u \rightarrow \infty} \frac{P(|\mathbf{X}| > tu)}{P(|\mathbf{X}| > u)} = t^{-\alpha} \quad (2)$$

Hence, roughly speaking, from the defining equation (1), the modulus and angular parts of the random vector, $|\mathbf{X}|$ and $\mathbf{X}/|\mathbf{X}|$, are *independent* in the limit,

that is,

$$P(\mathbf{X}/|\mathbf{X}| \in A | |\mathbf{X}| > u) \rightarrow P(\Theta \in A) \quad (3)$$

as $u \rightarrow \infty$

The distribution of Θ is often called the *spectral measure* of the regularly varying random vector. The modulus has power-law-like tails in the sense that

$$P(|\mathbf{X}| > x) = L(x)x^{-\alpha} \quad (4)$$

where $L(x)$ is a slowly varying function, that is, for any $t > 0$, $L(tx)/L(x) \rightarrow 1$ as $x \rightarrow \infty$. This property implies that the r th moments of $|\mathbf{X}|$ are infinite for $r > \alpha$ and finite for $r < \alpha$.

There is a second characterization of regular variation that is often useful in applications. Replacing u in equation (1) by the sequence $a_n > 0$ satisfying, $nP(|\mathbf{X}| > a_n) \rightarrow 1$ (i.e., we may take a_n to be the $1 - n^{-1}$ quantile of $|\mathbf{X}|$), we obtain

$$nP(|\mathbf{X}| > ta_n, \mathbf{X}/|\mathbf{X}| \in \cdot) \xrightarrow{v} t^{-\alpha} P(\Theta \in \cdot) \quad (5)$$

as $n \rightarrow \infty$

As expected, the multivariate regular variation condition collapses to the standard condition in the one-dimensional case $d = 1$. In this case, $\mathbb{S}^0 = \{-1, 1\}$, so that the random variable X is regular

varying if and only if $|X|$ is regularly varying

$$\lim_{u \rightarrow \infty} \frac{P(|X| > tu)}{P(|X| > u)} = t^{-\alpha} \quad (6)$$

and the tail balancing condition,

$$\begin{aligned} \lim_{u \rightarrow \infty} \frac{P(X > u)}{P(|X| > u)} &= p \quad \text{and} \\ \lim_{u \rightarrow \infty} \frac{P(X < -u)}{P(|X| > u)} &= q \end{aligned} \quad (7)$$

holds, where p and q are nonnegative constants with $p + q = 1$. The Pareto distribution, t -distribution, and nonnormal stable distributions are all examples of one-dimensional distributions that are regularly varying.

Example 1 (Independent components). Suppose that $\mathbf{X} = (X_1, X_2)'$ consists of two independent and identically distributed (i.i.d.) components, where X_1 is regularly varying random variable. The scatter plot of 10 000 replicates of these pairs, where X_1 has a t -distribution with 3 degrees of freedom, is displayed in Figure 2(a). The t -distribution is regularly varying, with index α being equal to the degrees of freedom. In this case, the spectral measure is a discrete distribution, which places equal mass at the intersection of

the unit circle and the coordinate axes. That is,

$$P\left(\Theta = \frac{\pi k}{2}\right) = \frac{1}{4} \quad \text{for } k = -1, 0, 1, 2 \quad (8)$$

The scatter plot in Figure 2 reflects the form of the spectral distribution. The points that are far from the origin occur only near the coordinate axes. The interpretation is that the probability that both components of the random vector are large at the same time is quite small.

Example 2 (Totally Dependent Components). In contrast to the independent case of Example 1, suppose that both components of the vector are identical, that is, $\mathbf{X} = (X, X)$, with X regularly varying in one dimension. Independent replicates of this random vector would just produce points lying on a 45° line through the origin. Here, it is easy to see that the vector is regularly varying with spectral measure given by

$$P\left(\Theta = \frac{\pi}{4}\right) = p \quad \text{and} \quad P\left(\Theta = \frac{-\pi}{4}\right) = q \quad (9)$$

Example 3 (AR(1) Process). Let $\{X_t\}$ be the AR(1) process defined by the recursion:

$$X_t = 0.9X_{t-1} + Z_t \quad (10)$$

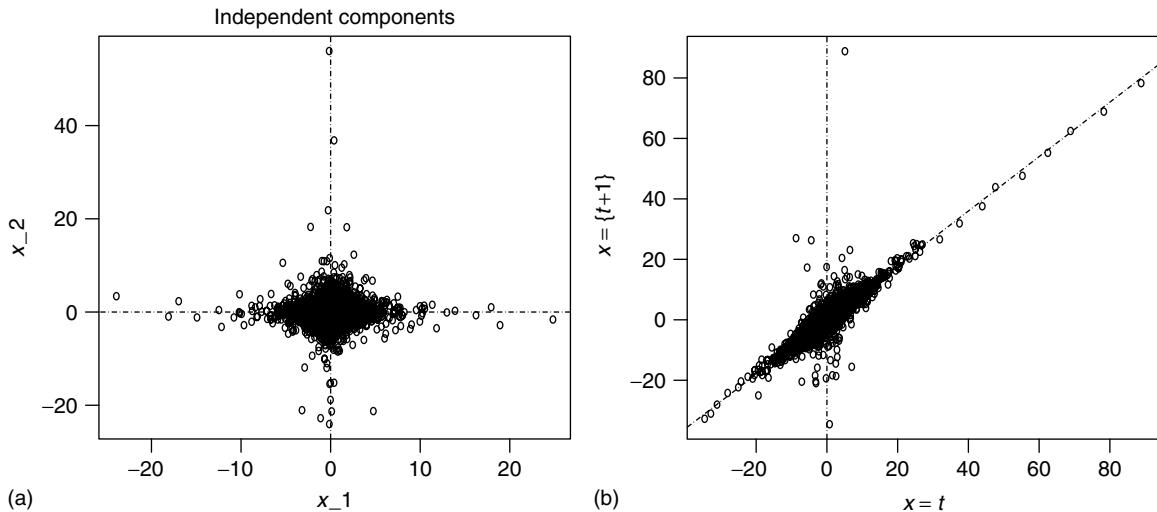

Figure 2 Scatter plot of 10 000 pairs of observations with i.i.d. components having a t -distribution with 3 degrees of freedom (a) and 10 000 observations of (X_t, X_{t+1}) from an AR(1) process (b)

where $\{Z_t\}$ is an i.i.d. sequence of random variables that have a symmetric stable distribution with exponent 1.8. This stable distribution is regularly varying with index $\alpha = 1.8$. Since $X_t = \sum_{j=0}^{\infty} 0.9^j Z_{t-j}$ is a linear process, it follows [14, 15] that X_t is also symmetric and regularly varying with index 1.8. In fact, X_t has a symmetric stable distribution with exponent 1.8 and scale parameter $(1 - 0.9^{1.8})^{-1/1.8}$. The scatter plot of consecutive observations (X_t, X_{t+1}) based on 10 000 observations generated from an AR(1) process is displayed in Figure 2(b). It can be shown that all finite-dimensional distributions of this time series are regularly varying. The spectral distribution of the vector consisting of two consecutive observations $\mathbf{X} = (X_t, X_{t+1})$ is given by

$$\begin{aligned} P(\Theta = \pm \arctan(0.9)) &= 0.9898 \quad \text{and} \\ P(\Theta = \pm \pi/2) &= 0.0102 \end{aligned} \quad (11)$$

As seen in Figure 2, one can see that most of the points in the scatter plot, especially those far from the origin, cluster tightly around the line through the origin with slope 0.9. This corresponds to the large mass at $\arctan(0.9)$ of the distribution of Θ . One can also detect a smattering of extreme points clustered around the vertical axis.

Estimation of α

A great deal of attention in the extreme value theory community has been devoted to the estimation of α in the regular variation condition (1). The generic Hill estimate is often a good starting point for this task. There are more sophisticated versions of Hill estimates, see [23] for a nice treatment of Hill estimators, but for illustration we stick with the standard version. For observations $X_1, \dots, X_n$ from a nonnegative-valued time series, let $X_{n:1} > \dots > X_{n:n}$ be the corresponding descending order statistics. If the data were in fact i.i.d. from a Pareto distribution, then the maximum likelihood estimator of α^{-1} based on the largest $m + 1$ order statistics is

$$\hat{\alpha}^{-1} = \frac{1}{m} \sum_{j=1}^m (\ln X_{n:j} - \ln X_{n:m+1}) \quad (12)$$

Different values of m produce an array of α estimates. The typical operating procedure is to plot the estimate of α versus m and choose a value

of m where the plot appears horizontal for an extended segment. See [7, 37] for other procedures for selecting m . There is the typical bias versus variance trade-off, with larger m producing smaller variance but larger bias. Figure 3 contains graphs of the Hill estimate of α as a function of m for the two simulated series in Figure 2 and the exchange rate and log-return data of Figure 1. In all cases, one can see a range of m for which the graph of $\hat{\alpha}$ is relatively flat. Using this segment as an estimate of α , we would estimate the index as approximately 3 for the two simulated series, approximately 3 for the exchange rate data, and around 3.5 for the stock price data. (The value of α for the two simulated series is indeed 3.) Also displayed on the plots are 95% confidence intervals for α , assuming the data are i.i.d. As suggested by these plots, the return data appear to have quite heavy tails.

Estimation of the Spectral Distribution

Using property (3), a naive estimate of the distribution of Θ is based on the angular components $\mathbf{X}_t/|\mathbf{X}_t|$ in the sample. One simply uses the empirical distribution of these angular pieces for which the modulus $|\mathbf{X}_t|$ exceeds some large threshold. More details can be found in [37]. For the scatter plots in Figure 2, we produced in Figure 4 kernel density estimates of the spectral density function for the random variable Θ on $(-\pi, \pi]$. One can see in the graph of the i.i.d. data, the large spikes at values of $\theta = -\pi, -\pi/2, 0, \pi/2, \pi$ corresponding to the coordinate axes (the values at $-\pi$ and π should be grouped together). On the other hand for the AR(1) process, the density estimate puts large mass at $\theta = \arctan(0.9)$ and $\theta = \arctan(0.9) - \pi$ corresponding to the line with slope 0.9 in the first and third quadrants, respectively. Since there are only a few points on the vertical axis, the density estimate does not register much mass at 0 and π .

Regular Variation for GARCH and SV Processes

GARCH Processes

The autoregressive conditional heteroscedastic (ARCH) process developed by Engle [19] and its generalized version, GARCH, developed by Engle

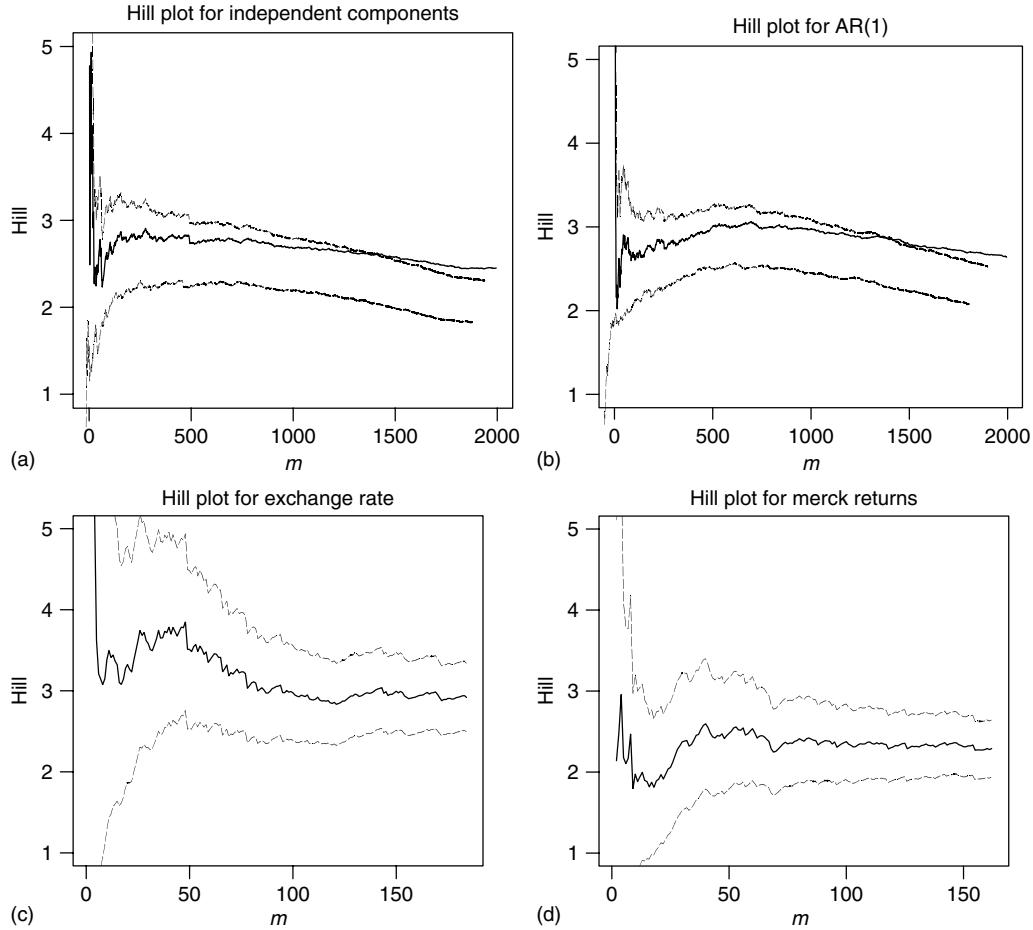

Figure 3 Hill plots for tail index: (a) i.i.d. data in Figure 2; (b) AR(1) process in Figure 2; (c) log-returns for US/pound exchange rate; and (d) log-returns for Merck stock, January 2, 2003 to April 28, 2006

and Bollerslev [20] are perhaps the most popular models for financial time series (see **GARCH Models**). Although there are many variations of the GARCH process, we focus on the traditional version. We say that $\{X_t\}$ is a GARCH(p, q) process if it is a strictly stationary solution of the equations:

$$\begin{aligned} X_t &= \sigma_t Z_t \\ \sigma_t^2 &= \alpha_0 + \sum_{i=1}^p \alpha_i X_{t-i}^2 \\ &\quad + \sum_{j=1}^q \beta_j \sigma_{t-j}^2, \quad t \in \mathbb{Z} \end{aligned} \quad (13)$$

where the *noise* or *innovations* sequence $(Z_t)_{t \in \mathbb{Z}}$ is an i.i.d. sequence with mean zero and unit variance. It is usually assumed that all coefficients α_i and β_j are nonnegative, with $\alpha_0 > 0$. For identification purposes, the variance of the noise is assumed to be 1 since otherwise its standard deviation can be absorbed into σ_t . (σ_t) is referred to as the *volatility* sequence of the GARCH process.

The parameters are typically chosen to ensure that a causal and strictly stationary solution to the equations (13) exists. This means that X_t has a representation as a measurable function of the past and present noise values $Z_s, s \leq t$. The necessary and sufficient conditions for the existence and uniqueness of a stationary ergodic solution to equation (13) are

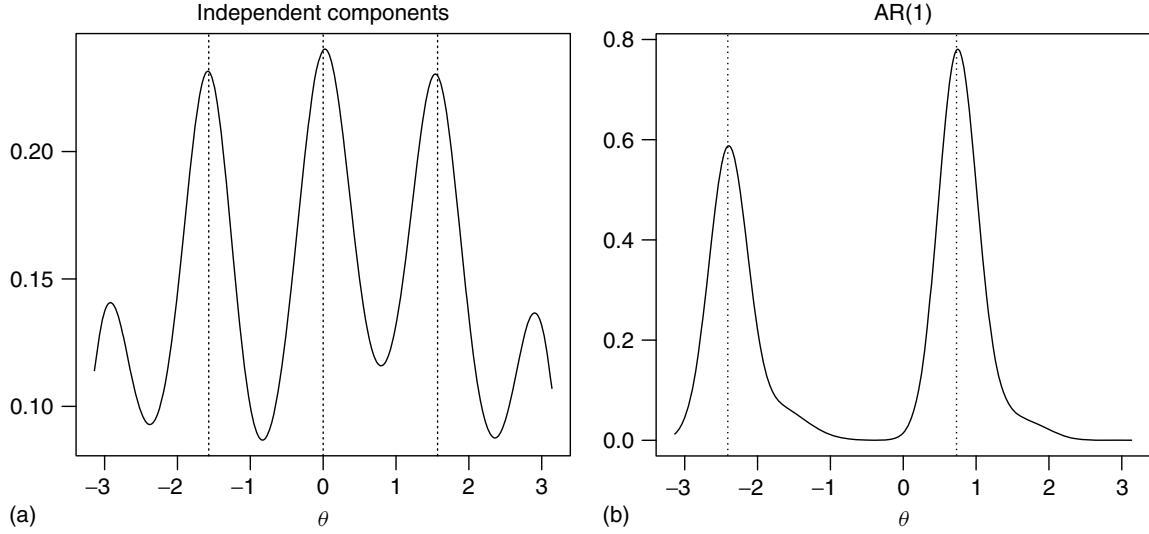

Figure 4 The estimation of the spectral density function for i.i.d. components (a) and for the AR(1) process (b) from Figure 2

given in [35] for the GARCH(1, 1) case and for the general GARCH(p, q) case in [4]; see [30] for a summary of the key properties of a GARCH process. In some cases, one only assumes weak stationarity, in which case the conditions on the parameters reduce substantially. A GARCH process is weakly stationary if and only if

$$\alpha_0 > 0 \quad \text{and} \quad \sum_{j=1}^p \alpha_j + \sum_{j=1}^q \beta_j < 1 \quad (14)$$

To derive properties of the tail of the finite-dimensional distributions of a GARCH process, including the marginal distribution, it is convenient to embed the squares X_t^2 and σ_t^2 in a stochastic recurrence equation (SRE). This embedding can be used to derive other key properties of the process beyond the finite-dimensional distributions. For example, conditions for stationarity and β -mixing can be established from the properties of SREs and general theory of Markov chains. Here, we focus on the tail behavior.

One builds an SRE by including the volatility process in the state vector. An SRE takes the form

$$\mathbf{Y}_t = \mathbf{A}_t \mathbf{Y}_{t-1} + \mathbf{B}_t \quad (15)$$

where $\mathbf{Y}_t$ is an m -dimensional random vector, $\mathbf{A}_t$ is an $m \times m$ random matrix, $\mathbf{B}_t$ is a random vector, and $\{(\mathbf{A}_t, \mathbf{B}_t)\}$ is an i.i.d. sequence. Under suitable conditions on the coefficient matrices and error matrices, one can derive various properties about the Markov chain $\mathbf{Y}_t$. For example, iteration of equation (15) yields a unique stationary and causal solution:

$$\mathbf{Y}_t = \mathbf{B}_t + \sum_{i=1}^{\infty} \mathbf{A}_t \cdots \mathbf{A}_{t-i+1} \mathbf{B}_{t-i}, \quad t \in \mathbb{Z} \quad (16)$$

To ensure almost surely (a.s.) convergence of the infinite series in equation (16), and hence the existence of a unique strictly stationary solution to equation (15), it is assumed that the *top Lyapunov exponent* given by

$$\gamma = \inf_{n \geq 1} n^{-1} E \log \|\mathbf{A}_n \cdots \mathbf{A}_1\| \quad (17)$$

is negative, where $\|\cdot\|$ is the operator norm corresponding to a given norm in $\mathbb{R}^m$.

Now, the GARCH process, at least its squares, can be embedded into an SRE by choosing

$$\mathbf{Y}_t = \begin{pmatrix} \sigma_{t+1}^2 \\ \vdots \\ \sigma_{t-q+2}^2 \\ X_t^2 \\ \vdots \\ X_{t-p+1}^2 \end{pmatrix}, \quad \mathbf{A}_t = \begin{pmatrix} \alpha_1 Z_t^2 + \beta_1 & \beta_2 & \cdots & \beta_{q-1} & \beta_q & \alpha_2 & \alpha_3 & \cdots & \alpha_p \\ 1 & 0 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 0 & 0 & 0 & \cdots & 0 \\ Z_t^2 & 0 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & 0 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 1 & 0 \end{pmatrix}$$

$$\mathbf{B}_t = (\alpha_0, 0, \dots, 0)' \quad (18)$$

where, as required, $\{(\mathbf{A}_t, \mathbf{B}_t)\}$ is an i.i.d. sequence. The top row in the SRE for the GARCH specification follows directly from the definition of the squared volatility process σ_{t+1}^2 and the property that $X_t = \sigma_t Z_t$.

In general, the top Lyapunov coefficient γ for the GARCH SRE cannot be calculated explicitly. However, a sufficient condition for $\gamma < 0$ is given as

$$\sum_{i=1}^p \alpha_i + \sum_{j=1}^q \beta_j < 1 \quad (19)$$

see p. 122 [4]. It turns out that this condition is also necessary and sufficient for the existence of a weakly stationary solution to the GARCH recursions. The solution will also be strictly stationary in this case.

It has been noted that for many financial time series, the GARCH(1,1) often provides an adequate model or is at least a good starter model. This is one of the few models where the Lyapunov coefficient can be computed explicitly. In this case, the SRE equation essentially collapses to the one-dimensional SRE given as

$$\sigma_{t+1}^2 = \alpha_0 + (\alpha_1 Z_t^2 + \beta_1) \sigma_t^2 = A_t \sigma_t^2 + \alpha_0 \quad (20)$$

where $A_t = \alpha_1 Z_t^2 + \beta_1$. The elements in the second row in the vector and matrix components of equation (18) play no role in this case. Hence,

$$\begin{aligned} \gamma &= n^{-1} E \log (A_n \cdots A_1) = E \log A_1 \\ &= E \log (\alpha_1 Z^2 + \beta_1) \end{aligned} \quad (21)$$

The conditions [35], $E \log(\alpha_1 Z^2 + \beta_1) < 0$ and $\alpha_0 > 0$, are necessary and sufficient for the existence of a stationary causal nondegenerate solution to the GARCH(1,1) equations.

Once the squares and volatility sequence, X_t^2 and σ_t^2 , respectively, are embedded in an SRE, then one can apply classical theory for SREs as developed by Kesten [28], (see also [22]), and extended by Basrak *et al.* [2], to establish regular variation of the tails of X_t^2 and σ_t^2 . The following result by Basrak *et al.* [1] summarizes the key results applied to a GARCH process.

Theorem 1 *Consider the process $(\mathbf{Y}_t)$ in equation (18) obtained from embedding a stationary GARCH process into the SRE (18). Assume that Z has a positive density on $\mathbb{R}$ such that $E(|Z|^h) < \infty$ for $h < h_0$ and $E(|Z|^{h_0}) = \infty$ for some $h_0 \in (0, \infty]$. Then with $\mathbf{Y} = \mathbf{Y}_1$, there exist $\alpha > 0$, a constant $c > 0$, and a random vector Θ on the unit sphere $\mathbb{S}^{p+q-2}$ such that*

$$x^{\alpha/2} P(|\mathbf{Y}| > x) \rightarrow c \quad \text{as } x \rightarrow \infty \quad (22)$$

and for every $t > 0$

$$\frac{P(|\mathbf{Y}| > tx, \mathbf{Y}/|\mathbf{Y}| \in \cdot)}{P(|\mathbf{Y}| > x)} \xrightarrow{w} t^{-\alpha/2} P(\Theta \in \cdot) \quad \text{as } x \rightarrow \infty \quad (23)$$

where $\xrightarrow{w}$ denotes weak convergence on the Borel σ -field of $\mathbb{S}^{p+q-2}$.^a

It follows that the components of the vector of $\mathbf{Y}$ are also regularly varying so that

$$\begin{aligned} P(|X_1| > x) &\sim c_1 x^{-\alpha} \quad \text{and} \\ P(\sigma_1 > x) &\sim c_2 x^{-\alpha} \end{aligned} \quad (24)$$

for some positive constants c_1 and c_2 . A straightforward application of Breiman's lemma [6], (cf. [13], Section 4), allows us to remove the absolute values in X_1 to obtain

$$\begin{aligned} P(X_1 > x) &= P(\sigma_1 Z_1^+ > x) \\ &\sim E((Z_1^+)^{\alpha}) P(\sigma_1 > x) \end{aligned} \quad (25)$$

$$\begin{aligned} P(X_1 \leq -x) &= P(-\sigma_1 Z_1^- \leq -x) \\ &\sim E((Z_1^-)^{\alpha}) P(\sigma_1 > x) \end{aligned} \quad (26)$$

where $Z_1^{\pm}$ are the respective positive and negative parts of Z_1 . With the exception of simple models such as the GARCH(1,1), there is no explicit formula for the index α of regular variation of the marginal distribution. In principle, α could be estimated from the data using a Hill style estimator, but an enormous sample size would be required in order to obtain a precise estimate of the index.

In the GARCH(1,1) case, α is found by solving the following equation:

$$E[(\alpha_1 Z^2 + \beta_1)^{\alpha/2}] = 1 \quad (27)$$

This equation can be solved for α by numerical and/or simulation methods for fixed values of α_1 and β_1 from the stationarity region of a GARCH(1,1) process and assuming a concrete density for Z . (See [12] for a table of values of α for various choices of α_1 and β_1 .) Note that in the case of an integrated GARCH (IGARCH) process where $\alpha_1 + \beta_1 = 1$, then we have $\alpha = 2$. This holds regardless of the distribution of Z_1 , provided it has a finite variance. Since the marginal distribution of an IGARCH process has Pareto-like tails with index 2, the variance is infinite.

While equations (25) and (26) describe only the regular variation of the marginal distribution, it is also true that the finite-dimensional distributions are regularly varying. To see this in the GARCH(1,1) case, we note that the volatility process is given as

$$\sigma_{t+1}^2 = (\alpha_1 Z_t^2 + \beta_1) \sigma_t^2 + \beta_0 \quad (28)$$

so that

$$\begin{aligned} (\sigma_1^2, \dots, \sigma_m^2) &= (1, \alpha_1 Z_1^2 + \beta_1, (\alpha_1 Z_2^2 + \beta_1) \\ &\quad \times (\alpha_1 Z_1^2 + \beta_1), \dots, \alpha_1 Z_{m-1}^2 + \beta_1) \cdots \\ &\quad \times (\alpha_1 Z_1^2 + \beta_1) \sigma_1^2 + \mathbf{R}_m \\ &= \mathbf{D}_m \sigma_1^2 + \mathbf{R}_m \end{aligned} \quad (29)$$

where $\mathbf{R}_m$ has tails that are lighter than those for σ_1^2 . Now since $\mathbf{D}_m = (D_1, \dots, D_m)$ is independent of σ_1^2 and has a $\alpha/2 + \delta$ moment for some $\delta > 0$, it follows by a generalization of Breiman's lemma [1] that

$$\mathbf{U}_m := (X_1^2, \dots, X_m^2) = \mathbf{F}_m \sigma_1^2 + \mathbf{R}_m \quad (30)$$

where $\mathbf{F}_m = (Z_1^2 D_1, \dots, Z_m^2 D_m)$ is regularly varying with

$$\begin{aligned} \lim_{x \rightarrow \infty} \frac{P(|\mathbf{U}_m| > x, \mathbf{U}_m/|\mathbf{U}_m| \in A)}{P(|\mathbf{U}_m| > x)} \\ &= \lim_{x \rightarrow \infty} \frac{P(|\mathbf{F}_m| \sigma_1^2 > x, \mathbf{F}_m/|\mathbf{F}_m| \in A)}{P(|\mathbf{F}_m| \sigma_1^2 > x)} \\ &= \frac{E(|\mathbf{F}_m|^{\alpha/2} I_A(\mathbf{F}_m/|\mathbf{F}_m|))}{E|\mathbf{F}_m|^{\alpha/2}} \end{aligned} \quad (31)$$

It follows that the finite-dimensional distributions of a GARCH process are regularly varying.

Stochastic Volatility Processes

The SV process also starts with the multiplicative model (13)

$$X_t = \sigma_t Z_t \quad (32)$$

with (Z_t) being an i.i.d. sequence of random variables. If $\text{var}(Z_t) < \infty$, then it is conventional to assume that Z_t has mean 0 and variance 1. Unlike the GARCH process, the volatility process (σ_t) for SV processes is assumed to be independent of the sequence (Z_t) . Often, one assumes that $\log \sigma_t^2$ is a linear Gaussian process given by

$$\log \sigma_t^2 = Y_t = \mu + \sum_{j=0}^{\infty} \psi_j \eta_{t-j} \quad (33)$$

where (ψ_j) is a sequence of square summable coefficients and (η_t) is a sequence of i.i.d. $N(0, \sigma^2)$ random variables independent of (Z_t) . If $\text{var}(Z_t)$ is

finite and equal to 1, then the SV process $X_t = \sigma_t Z_t = \exp^{Y_t/2} Z_t$ is white noise with mean 0 and variance $\exp\{\mu + \sigma^2 \sum_{j=0}^{\infty} \psi_j^2/2\}$. One advantage of such processes is that one can explicitly compute the autocovariance function (ACVF) of any power of X_t and its absolute values. For example, the ACVF of the squares of (X_t) is, for $h > 0$, given as

$$\begin{aligned} \gamma_{|X|^2}(h) &= E(\exp\{Y_0 + Y_h\}) - (E \exp\{Y_0\})^2 \\ &= \exp\left\{2\mu + \sigma^2 \sum_{i=0}^{\infty} \psi_i^2\right\} \\ &\quad \times \left[\exp\left\{\sigma^2 \sum_{i=0}^{\infty} \psi_i \psi_{i+h}\right\} - 1\right] \\ &= e^{2\mu} e^{\gamma_Y(0)} \left[e^{\gamma_Y(h)} - 1\right] \end{aligned} \quad (34)$$

Note that as $h \rightarrow \infty$,

$$\gamma_{|X|^2}(h) \sim e^{2\mu} e^{\gamma_Y(0)} \left[e^{\gamma_Y(h)} - 1\right] \sim e^{2\mu} e^{\gamma_Y(0)} \gamma_Y(h) \quad (35)$$

so that the ACVF of the SV for the squares converges to zero at the same rate as the log-volatility process.

If Z_t has a Gaussian distribution, then the tail of X_t remains light although a bit heavier than a Gaussian [3]. This is in contrast to the GARCH case where an i.i.d. Gaussian input leads to heavy-tailed marginals of the process. On the other hand, for SV processes, if the Z_t have heavy tails, for example, if Z_t has a t -distribution, then Davis and Mikosch [10] show that X_t is regularly varying. Furthermore, in this case, any finite collection of X_t 's has the same limiting joint tail behavior as an i.i.d. sequence with regularly varying marginals. Specifically, the two random vectors, $(X_1, \dots, X_k)'$ and $(E|\sigma_1|^\alpha)^{1/\alpha} (Z_1, \dots, Z_k)'$ have the same joint tail behavior.

Limit Theory GARCH and SV Processes

Convergence of Maxima

If (X_t) is a stationary sequence of random variables with common distribution function F , then often one can directly relate the limiting distribution of the maxima, $M_n = \max\{X_1, \dots, X_n\}$ to F . Assuming

that X_1 is regularly varying with index $-\alpha$ and choosing the sequence (a_n) such that $n(1 - F(a_n)) \rightarrow 1$, then

$$F^n(a_n x) \rightarrow G(x) = \begin{cases} 0, & x \leq 0 \\ e^{-x^{-\alpha}}, & x > 0 \end{cases} \quad (36)$$

This relation is equivalent to convergence in distribution of the maxima of the associated independent sequence $(\hat{X}_t)$ (i.e., the sequence $(\hat{X}_t)$ is i.i.d. with common distribution function F) normalized by a_n to the Fréchet distribution G . Specifically, if $\hat{M}_n = \max\{\hat{X}_1, \dots, \hat{X}_n\}$, then

$$P(a_n^{-1} M_n \leq x) \rightarrow G(x) \quad (37)$$

Under mild mixing conditions on the sequence (X_t) [29], we have

$$P(a_n^{-1} M_n \leq x) \rightarrow H(x) \quad (38)$$

with H a nondegenerate distribution function if and only if

$$H(x) = G^\theta(x) \quad (39)$$

for some $\theta \in (0, 1]$. The parameter θ is called the *extremal index* and can be viewed as a sample size adjustment for the maxima of the dependent sequence due to clustering of the extremes. The case $\theta = 1$ corresponds to no clustering, in which case the limiting behavior of M_n and $\hat{M}_n$ are identical. In case $\theta < 1$, M_n behaves asymptotically like the maximum of $n\theta$ independent observations. The reciprocal of the extremal index $1/\theta$ of a stationary sequence (X_t) also has the interpretation as the expected size of clusters of high-level exceedances in the sequence.

There are various sufficient conditions for ensuring that $\theta = 1$. Perhaps the most common anticlustering condition is D' [28], which has the following form:

$$\limsup_{n \rightarrow \infty} n \sum_{t=2}^{[n/k]} P(X_1 > a_n x, X_t > a_n x) = O(1/k) \quad (40)$$

as $k \rightarrow \infty$. Hence, if the stationary process (X_t) satisfies a mixing condition and D' , then

$$P(a_n^{-1} M_n \leq x) \rightarrow G(x) \quad (41)$$

Returning to the GARCH setting, we assume that the conditions of Theorem 1 are satisfied. Then we know that $P(|X| > x) \sim c_1 x^{-\alpha}$ for some $\alpha, c_1 > 0$, and we can even specify the value of α in the GARCH(1, 1) case by solving equation (27). Now choosing $a_n = n^{1/\alpha} c_1^{1/\alpha}$, we have $nP(|X_1| > a_n) \rightarrow 1$ and defining $M_n = \max\{|X_1|, \dots, |X_n|\}$, we obtain

$$P(a_n^{-1} M_n \leq x) \rightarrow \exp\{-\theta_1 x^{-\alpha}\} \quad (42)$$

where the extremal index θ_1 is strictly less than 1. Explicit formulae for the extremal index of a general GARCH process are hard to come by. In some special cases, such as the ARCH(1) and the GARCH(1,1), there are more explicit expressions. For example, in the GARCH(1,1) case, the extremal index θ_1 for the maxima of the absolute values of the GARCH process is given by Mikosch and Stărică [34]

$$\theta_1 = \frac{\lim_{k \rightarrow \infty} E \left(|Z_1|^\alpha - \max_{j=2, \dots, k+1} \left| Z_j^2 \prod_{i=2}^j A_i \right|^{\alpha/2} \right)}{E|Z_1|^\alpha} \quad (43)$$

The above expression can be evaluated by Monte-Carlo simulation, see, for example, [25] for the ARCH(1) case with standard normal noise Z_t ; see [18], Section 8.1, where one can also find some advice as to how the extremal index of a stationary sequence can be estimated from data.

The situation is markedly different for SV processes. For the SV process with either light- or heavy-tailed noise, one can show that D' is satisfied and hence the extremal index is always 1 (see [3] for the light-tailed case and [10] for the heavy-tailed case). Hence, although both GARCH and SV models exhibit stochastic clustering, only the GARCH process displays extremal clustering.

Convergence of Point Processes

The theory of point processes plays a central role in extreme value theory and in combination with regular variation can be a powerful tool for establishing limiting behavior of other statistics beyond extreme order statistics. As in the previous section, suppose that $(\hat{X}_t)$ is an i.i.d. sequence of nonnegative random variables with common distribution F that has

regularly varying tails with index $-\alpha$. Choosing the sequence a_n satisfying $n(1 - F(a_n)) \rightarrow 1$, we have

$$nP(\hat{X}_1 > a_n x) \rightarrow x^{-\alpha} \quad (44)$$

as $n \rightarrow \infty$. Now equation (44) can be strengthened to the statement

$$nP(a_n^{-1} \hat{X}_1 \in B) \rightarrow \nu(B) \quad (45)$$

for all suitably chosen Borel sets B , where the measure ν is defined by its value on intervals of the form $(a, b]$ with $a > 0$ as

$$\nu(a, b] = a^{-\alpha} - b^{-\alpha} \quad (46)$$

The convergence in equation (46) can be connected with the convergence in the distribution of a sequence of point processes. For a bounded Borel set B in $E = [0, \infty] \setminus \{0\}$, define the sequence of point processes $(\hat{N}_n)$ by

$$\hat{N}_n(B) = \# \{a_n^{-1} \hat{X}_j \in B, j = 1, 2, \dots, n\} \quad (47)$$

If B is the interval $(a, b]$ with $0 < a < b \leq \infty$, then since the $\hat{X}_j$ are i.i.d., $\hat{N}_n(B)$ has a binomial distribution with number of trials n and probability of success

$$p_n = P(a_n^{-1} \hat{X}_1 \in (a, b]) \quad (48)$$

It then follows from equation (46) that $\hat{N}_n(B)$ converges in distribution to a Poisson random variable $N(B)$ with mean $\nu(B)$. In fact, we have the stronger point process convergence:

$$\hat{N}_n \xrightarrow{d} N \quad (49)$$

where N is a Poisson process on E with mean measure $\nu(dx)$ and $\xrightarrow{d}$ denotes convergence in distribution of point processes. For our purposes, $\xrightarrow{d}$ for point processes means that for any collection of *bounded*^b Borel sets $B_1, \dots, B_k$ for which $P(N(\partial B_j) > 0) = 0$, $j = 1, \dots, k$, we have

$$(\hat{N}_n(B_1), \dots, \hat{N}_n(B_k)) \xrightarrow{d} (N(B_1), \dots, N(B_k)) \quad (50)$$

on $\mathbb{R}^k$ [18, 29, 36].

As an application of equation (49), define $\hat{M}_{n,k}$ to be the k th largest among $\hat{X}_1, \dots, \hat{X}_n$. For $y \leq x$, the event $\{a_n^{-1}\hat{M}_n \leq x, a_n^{-1}\hat{M}_{n,k} \leq y\} = \{\hat{N}_n(x, \infty) = 0, \hat{N}_n(y, x] \leq k-1\}$ and hence

$$\begin{aligned} P(a_n^{-1}\hat{M}_n \leq x, a_n^{-1}\hat{M}_{n,k} \leq y) \\ &= P(\hat{N}_n(x, \infty) = 0, \hat{N}_n(y, x] \leq k-1) \\ &\rightarrow P(N(x, \infty) = 0, N(y, x] \leq k-1) \\ &= e^{-x^{-\alpha}} \sum_{j=0}^{k-1} (y^{-\alpha} - x^{-\alpha})^j / j! \end{aligned} \quad (51)$$

As a second application of the limiting Poisson convergence in equation (49), the limiting Poisson process $\hat{N}$ has points located at $\Gamma_k^{-1/\alpha}$, where $\Gamma_k = E_1 + \dots + E_k$ is the sum of k i.i.d. unit exponentially distributed random variables. Then if $\alpha < 1$, the result is more complicated; if $\alpha \geq 1$, we obtain the convergence of partial sums:

$$a_n^{-1} \sum_{t=1}^n \hat{X}_t \xrightarrow{d} \sum_{j=0}^{\infty} \Gamma_j^{-1/\alpha} \quad (52)$$

In other words, the sum of the points of the point process N_n converges in distribution to the sum of points in the limiting Poisson process.

For a stationary time series (X_t) with heavy tails that satisfy a suitable mixing condition, such as strong mixing, and the anticlustering condition D' , then the convergence in equation (49) remains valid, as well as the limit in equation (52), at least for positive random variables. For example, this is the case for SV processes. If the condition D' is replaced by the assumption that all finite-dimensional random variables are regularly varying, then there is a point convergence result for N_n corresponding to (X_t) . However, the limit point process in this case is more difficult to describe. Essentially, the point process has anchors located at the Poisson points $\Gamma_j^{-1/\alpha}$. At each of these anchor locations, there is an independent cluster of points that can be described by the distribution of the angular measures in the regular variation condition [8, 9]. These conditions can then be applied to functions of the data, such as lagged products, to establish the convergence in distribution of the sample autocovariance function. This is the subject of the following section.

The Behavior of the Sample Autocovariance and Autocorrelation Functions

The ACF is one of the principal tools used in classical time series modeling. For a stationary Gaussian process, the dependence structure of the process is completely determined by the ACF. The ACF also conveys important dependence information for linear process. To some extent, the dependence governed by a linear filter can be fully recovered from the ACF. For the time series consisting of financial returns, the data are uncorrelated, so the value of the ACF is substantially diminished. Nevertheless, the ACF of other functions of the process such as the squares and absolute values can still convey useful information about the nature of the nonlinearity in the time series. For example, slow decay of the ACF of the squares is consistent with the volatility clustering present in the data. For a stationary time series (X_t) , the ACVF and ACF are defined as

$$\begin{aligned} \gamma_X(h) &= \text{cov}(X_0, X_h) \quad \text{and} \\ \rho_X(h) &= \text{corr}(X_0, X_h) = \frac{\gamma_X(h)}{\gamma_X(0)}, \quad h \geq 0 \end{aligned} \quad (53)$$

respectively. Now for observations $X_1, \dots, X_n$ from the stationary time series, the ACVF and ACF are estimated by their sample counterparts, namely, by

$$\hat{\gamma}_X(h) = \frac{1}{n} \sum_{t=1}^{n-h} (X_t - \bar{X}_n)(X_{t+h} - \bar{X}_n) \quad (54)$$

and

$$\hat{\rho}_X(h) = \frac{\hat{\gamma}_X(h)}{\hat{\gamma}_X(0)} = \frac{\sum_{t=1}^{n-h} (X_t - \bar{X}_n)(X_{t+h} - \bar{X}_n)}{\sum_{t=1}^n (X_t - \bar{X}_n)^2} \quad (55)$$

where $\bar{X}_n = n^{-1} \sum_{t=1}^n X_t$ is the sample mean.

Even though the sample ACVF is an average of random variables, its asymptotic behavior is determined by the extremes values, at least in the case of heavy-tailed data. Regular variation and point process theory are the two ingredients that play a key role in deriving limit theory for the sample ACVF and ACF. In particular, one applies the point process techniques alluded to in the previous section to the

stationary process consisting of products $(X_t X_{t+h})$. The first such results were established by Davis and Resnick [14–16] in a linear process setting. Extensions by Davis and Hsing [8] and Davis and Mikosch [9] allowed one to consider more general time series models beyond those linear. The main idea is to consider a point process N_n based on products of the form $X_t X_{t+h}/a_n^2$. After establishing convergence of this point process, in many cases one can apply the continuous mapping theorem to show that the sum of the points that comprise N_n converges in distribution to the sum of the points that make up the limiting point process. Although the basic idea for establishing these results is rather straightforward, the details are slightly complex. These ideas have been applied to the case of GARCH processes in [1] and to SV processes in [10], which are summarized below.

The GARCH Case

The scaling in the limiting distribution for the sample ACF depends on the index of regular variation α specified in Theorem 1. We summarize the results for the various cases of α .

1. If $\alpha \in (0, 2)$, then $\hat{\rho}_X(h)$ and $\hat{\rho}_{|X|}(h)$ have nondegenerate limit distributions. The same statement holds for $\hat{\rho}_{X^2}(h)$ when $\alpha \in (0, 4)$.
2. If $\alpha \in (2, 4)$, then both $\hat{\rho}_X(h)$, $\hat{\rho}_{|X|}(h)$ converge in probability to their deterministic counterparts $\rho_X(h)$, $\rho_{|X|}(h)$, respectively, at the rate $n^{1-2/\alpha}$ and the limit distribution is a complex function of non-Gaussian stable random variables.
3. If $\alpha \in (4, 8)$, then

$$n^{1-4/(2\alpha)}(\hat{\rho}_{X^2}(h) - \rho_{X^2}(h)) \xrightarrow{d} S_{\alpha/2}(h) \quad (56)$$

where the random variable $S_{\alpha/2}(h)$ is a function of infinite variance stable random variables.

4. If $\alpha > 4$, then the one can apply standard central limit theorems for stationary mixing sequences to establish a limiting normal distribution [17, 26]. In particular, $(\hat{\rho}_X(h))$ and $(\hat{\rho}_{|X|}(h))$ have Gaussian limits at $\sqrt{n}$ -rates. The corresponding result holds for (X_t^2) when $\alpha > 8$.

These results show that the limit theory for the sample ACF of a GARCH process is rather complicated when the tails are heavy. In fact, there is considerable empirical evidence based on extreme

value statistics as described in the second section, indicating that log-return series might not have a finite fourth or fifth moment^c and then the limit results above would show that the usual confidence bands for the sample ACF based on the central limit theorem and the corresponding $\sqrt{n}$ -rates are far too optimistic in this case.

The Stochastic Volatility Case

For a more direct comparison with the GARCH process, we choose a distribution for the noise process that matches the power law tail of the GARCH with index α . Then

$$\left(\frac{n}{\ln n}\right)^{1/\alpha} \hat{\rho}_X(h) \quad \text{and} \quad \left(\frac{n}{\ln n}\right)^{1/(2\alpha)} \hat{\rho}_{X^2}(h) \quad (57)$$

converge in distribution for $\alpha \in (0, 2)$ and $\alpha \in (0, 4)$, respectively. This illustrates the excellent large sample behavior of the sample ACF for SV models even if ρ_X and ρ_{X^2} are not defined [11, 13]. Thus, even if $\text{var}(Z_t) = \infty$ or $E Z_t^4 = \infty$, the estimates $\hat{\rho}_X(h)$ and $\hat{\rho}_{X^2}(h)$, respectively, converge to zero at a rapid rate. This is in marked contrast with the situation for GARCH processes, where under similar conditions on the marginal distribution, the respective sample ACFs converge in distribution to random variables without any scaling.

End Notes

^aBasrak *et al.* [1] proved this result under the condition that $\alpha/2$ is not an even integer. Boman and Lindskog [5] removed this condition.

^bHere bounded means bounded away from zero.

^cSee, for example, [18], Chapter 6, and [33].

Filtering

The Filtering Problem

Consider a randomly evolving system, the state of which is denoted by x_t and this state may not be directly observable. Denote by y_t the observation at time $t \in [0, T]$ (x_t and y_t may be vector-valued): y_t is supposed to be probabilistically related to x_t . For instance, y_t may represent a noisy measurement of x_t .

The process x_t is generally supposed to evolve in a Markovian way according to a given (*a priori*) distribution $p(x_t | x_s)$, $s \leq t$. The dynamics of y_t are given in terms of the process x_t ; a general assumption is that, given x_t , the process y_t is independent of its past and so one may consider as given the distribution $p(y_t | x_t)$. The information on x_t at a given $t \in [0, T]$ is thus represented by the past and present observations of y_t , that is, by $y_0^t := \{y_s; s \leq t\}$ or, equivalently, by the filtration $\mathcal{F}_t^y := \sigma\{y_s; s \leq t\}$. This information, combined with the *a priori* dynamics of x given by $p(x_t | x_s)$ can, via a Bayes-type formula, be synthesized in the conditional or posterior distribution $p(x_t | y_0^t)$ of x_t , given y_0^t , and this distribution is called the *filter distribution*.

The filtering problem consists now in determining, possibly in a recursive way, the filter distribution at each $t \leq T$. It can also be seen as a dynamic extension of Bayesian statistics: for $x_t \equiv x$ an unknown parameter, the dynamic model for x given by $p(x_t | x_s)$ reduces to a prior distribution for x and the filter $p(x | y_0^t)$ is then simply the posterior distribution of x , given the observations y_s , $s \leq t$.

In many applications, it suffices to determine a synthetic value of the filter distribution $p(x_t | y_0^t)$. In particular, given an (integrable) function $f(\cdot)$, one may want to compute

$$\begin{aligned} E\{f(x_t) | y_0^t\} &= E\{f(x_t) | \mathcal{F}_t^y\} \\ &= \int f(x) \, dp(x | y_0^t) \end{aligned} \quad (1)$$

The quantity in equation (1) may be seen as the best estimate of $f(x_t)$, given y_0^t , with respect to the mean square error criterion in the sense that $E\{(E\{f(x_t) | y_0^t\}) - f(x_t)\}^2 \leq E\{(g(y_0^t) - f(x_t))^2\}$ for all measurable (and integrable) functions $g(y_0^t)$ of the available information. In this sense, one may also consider

$E\{f(x_t) | \mathcal{F}_t^y\}$ as the *optimal filter* for $f(x_t)$. Notice that determining $E\{f(x_t) | \mathcal{F}_t^y\}$ is no more restrictive than determining the entire filter distribution $p(x_t | y_0^t)$; in fact, by taking $f(x) = e^{i\lambda x}$ for a generic λ , the $E\{f(x_t) | \mathcal{F}_t^y\}$ in equation (1) leads to the conditional characteristic function of x_t given y_0^t .

Related to the filtering problem, are the *prediction problem*, that is, that of determining $p(x_t | y_0^s)$ for $s < t$, and the *interpolation or smoothing problem* concerning $p(x_t | y_0^s)$ for $t < s$. Given the Bayesian nature of the filtering problem, one can also consider the so-called *combined filtering and parameter estimation problem*: if the dynamics $p(x_t | x_s)$ for x include an unknown parameter θ , one may consider the problem of determining the joint conditional distribution $p(x_t, \theta | \mathcal{F}_t^y)$.

Models for the Filtering Problem

To solve a given filtering problem, one has to specify the two basic inputs, namely, $p(x_t | x_s)$ and $p(y_t | x_t)$. A classical model in discrete time is

$$\begin{cases} x_{t+1} = a(t, x_t) + b(t, x_t) w_t \\ y_t = c(t, x_t) + v_t \end{cases} \quad (2)$$

where w_t and v_t are (independent) sequences of independent random variables and the distribution of x_0 is given. Notice that in equation (2) the process x_t is Markov and y_t represents the indirect observations of x_t , affected by additive noise.

The continuous time counterpart is

$$\begin{cases} dx_t = a(t, x_t) dt + b(t, x_t) dw_t \\ dy_t = c(t, x_t) dt + dv_t \end{cases} \quad (3)$$

and notice that, here, y_t represents the cumulative observations up to t . These basic models allow for various extensions: x_t may, for example, be a jump-diffusion process or a Markov process with a finite number of states, characterized by its transition intensities. Also the observations may more generally be a jump-diffusion such as

$$dy_t = c(t, x_t) dt + dv_t + dN_t \quad (4)$$

where N_t is a doubly stochastic Poisson process, the intensity $\lambda_t = \lambda(x_t)$ of which depends on x_t . Further generalizations are, of course, possible.

Analytic Solutions of the Filtering Problem

Discrete Time. By the Markov property of the process x_t and the fact that, given x_t , the process y_t is independent of its past, with the use of Bayes' formula one easily obtains the following two-step recursions

$$\begin{cases} p(x_t | y_0^{t-1}) = \int p(x_t | x_{t-1}) dp(x_{t-1} | y_0^{t-1}) \\ p(x_t | y_0^t) \propto p(y_t | x_t) p(x_t | y_0^{t-1}) \end{cases} \quad (5)$$

where $\propto$ denotes “proportional to” and the first step corresponds to the *prediction step* while the second one is the *updating step*. The recursions start with $p(x_0 | y_0^0) = p(x_0)$. Although equation (5) represents a fully recursive relation, its actual computation is made difficult not only by the presence of the integral in x_{t-1} , but also by the fact that this integral is parameterized by x_t that, in general, takes infinitely many values. Depending on the model, one can however obtain explicit solutions as will be shown below. The most general of such situations arises when one can find a finitely parameterized class of distributions of x_t that is closed under the operator implicit in equation (5), that is, such that, whenever $p(x_{t-1} | y_0^{t-1})$ belongs to this class, then $p(x_t | y_0^t)$ also belongs to it. A classical case is the linear conditionally Gaussian case that corresponds to a model of the form

$$\begin{cases} x_{t+1} = A_t(y_0^t)x_t + B_t(y_0^t)w_t \\ y_t = C_t(y_0^t)x_t + R_t(y_0^t)v_t \end{cases} \quad (6)$$

where the coefficients may depend on the entire past of the observations y_t , and w_t, v_t are independent i.i.d. sequences of standard Gaussian random variables. For such a model, $p(x_t | y_0^t)$ is Gaussian at each t and therefore characterized by mean and (co)variance that can be recursively computed by the well-known *Kalman–Bucy filter*. Denoting

$$\begin{aligned} \hat{x}_{t|t-1} &:= E\{x_t | y_0^{t-1}\}; \hat{x}_{t|t} := E\{x_t | y_0^t\} \\ P_{t|t-1} &:= E\{(x_t - \hat{x}_{t|t-1})(x_t - \hat{x}_{t|t-1})' | y_0^{t-1}\} \\ P_{t|t} &:= E\{(x_t - \hat{x}_{t|t})(x_t - \hat{x}_{t|t})' | y_0^t\} \end{aligned} \quad (7)$$

the Kalman–Bucy filter is given by (dropping for simplicity the dependence on y_0^t),

$$\begin{cases} \hat{x}_{t|t-1} = A_{t-1} \hat{x}_{t-1|t-1} \\ P_{t|t-1} = A_{t-1} P_{t-1|t-1} A_{t-1}' + B_{t-1} B_{t-1}' \end{cases} \quad (8)$$

which represents the *prediction step*, and

$$\begin{aligned} \hat{x}_{t|t} &= \hat{x}_{t|t-1} + L_t[y_t - C_t \hat{x}_{t|t-1}] \\ P_{t|t} &= P_{t|t-1} - L_t C_t P_{t|t-1} \end{aligned} \quad (9)$$

which represents the *updating step* with $\hat{x}_{0|-1}$ the mean of x_0 and $P_{0|-1}$ its variance. Furthermore,

$$L_t := P_{t|t-1} C_t' [C_t P_{t|t-1} C_t' + R_t R_t']^{-1} \quad (10)$$

Notice that, in the prediction step, the estimate of x_t is propagated one step further on the basis of the given *a priori* dynamics of x_t , while in the updating step one takes into account the additional information coming from the current observation. A crucial role in the updating step given by equation (9) is played by

$$\begin{aligned} y_t - C_t \hat{x}_{t|t-1} &= y_t - C_t A_{t-1} \hat{x}_{t-1|t-1} \\ &= y_t - C_t E\{x_t | y_0^{t-1}\} \\ &= y_t - E\{y_t | y_0^{t-1}\} \end{aligned} \quad (11)$$

which represents the new information given by y_t with respect to its best estimate $E\{y_t | y_0^{t-1}\}$ and is therefore called *innovation*.

The Kalman–Bucy filter has been extremely successful and has also been applied to Gaussian models that are nonlinear by simply linearizing the nonlinear coefficient functions around the current best estimate of x_t . In this way, one obtains an approximate filter, called the *extended Kalman filter*.

Exact solutions for the discrete time filtering problem can also be obtained for the case when x_t is a finite-state Markov chain with, say, N states defined by its transition probability matrix. In this case, the filter is characterized by its conditional state probability vector that we denote by $\pi_t = (\pi_t^1, \dots, \pi_t^N)$ with $\pi_t^i := P\{x_t = i | \mathcal{F}_t^y\}$.

Continuous Time. For the solution of a general continuous time problem, we have two main approaches, namely, the *innovations approach* that extends the innovation representation of the Kalman

filter where, combining equations (8) and (9), this latter representation is given by

$$\hat{x}_{t|t} = A_{t-1} \hat{x}_{t-1|t-1} + L_t [y_t - C_t A_{t-1} \hat{x}_{t-1|t-1}] \quad (12)$$

and the so-called *reference probability approach*. For the sake of brevity, we discuss here only the innovations approach (*Kushner–Stratonovich equation*) and we do it for the case of the model in equation (3) mentioning briefly possible extensions to other cases. For the reference probability approach (Zakai equation), we refer to the literature (for instance, [8, 19]).

We denote by $\mathcal{L}$ the generator of the Markov diffusion x_t in equation (3), that is, assuming $x \in \mathbb{R}^n$, for a function $\phi(t, x) \in \mathbb{C}^{1,2}$, we have

$$\begin{aligned} \mathcal{L}\phi(t, x) &= a(t, x)\phi_x(t, x) \\ &+ \frac{1}{2} \sum_{i,j=1}^n \sigma_{ij}(t, x)\phi_{x_i x_j}(t, x) \end{aligned} \quad (13)$$

with $\sigma(t, x) := b(t, x)b'(t, x)$. Furthermore, for a generic (integrable) $f(\cdot)$, we let $\hat{f}_t := E\{f(x_t) \mid \mathcal{F}_t^y\}$. The innovations approach now leads, in case of model given by equation (3), to the following dynamics, also called the *Kushner–Stratonovich equation* (see e.g., [19, 8]):

$$\begin{aligned} d\hat{f}_t &= \widehat{\mathcal{L}f(x_t)} dt + [c(t, \widehat{x_t})\widehat{f(x_t)} \\ &- c(t, \widehat{x_t})\hat{f}_t]' [dy_t - c(t, \widehat{x_t}) dt] \end{aligned} \quad (14)$$

which (see equation (3)) is based on the innovations $dy_t - c(t, \widehat{x_t}) dt = dy_t - E\{dy_t \mid \mathcal{F}_t^y\}$. In addition to the stochastic integral, the main difficulty with equation (14) is that, to compute $\hat{f}$, one needs $\widehat{cf}$, which, in turn, requires $\widehat{c^2 f}$, and so on. In other words, equation (14) is not a closed system of stochastic differential equations. Again, for particular models, equation (14) leads to a closed system as it happens with the linear-Gaussian version of equation (3) that leads to the continuous time Kalman–Bucy filter, which is analogous to its discrete time counterpart. A further case arises when x_t is finite-state Markov with transition intensity matrix $Q = \{q_{ij}\}$, $i, j = 1, \dots, N$. Putting $\pi_t(i) := P\{x_t = i \mid \mathcal{F}_t^y\}$ and taking $f(\cdot)$ as the indicator function of the various values of x_t ,

equation (14) becomes (on replacing $\mathcal{L}$ by Q)

$$\begin{aligned} d\pi_t(j) &= \sum_{i=1}^N \pi_t(i) q_{ij} dt \\ &+ \pi_t(j) \left[c(t, j) - \sum_{i=1}^N \pi_t(i) c(t, i) \right] \\ &\times \left[dy_t - \sum_{i=1}^N \pi_t(i) c(t, i) dt \right] \end{aligned} \quad (15)$$

For more results when x_t is finite-state Markov, we refer to [10], and, in particular, see [11].

We just mention that one can write the dynamics of $\hat{f}_t$ also in the case of jump-diffusion observations as in equation (4) (see [17]) and one can, furthermore, obtain an evolution equation, a stochastic partial differential equation (PDE), for the conditional density $p(x_t) = p(x_t \mid y_0^t)$, whenever it exists, that involves the formal adjoint $\mathcal{L}^*$ of the $\mathcal{L}$ in equation (13) (see [19]).

Numerical Solutions of the Filtering Problem

As we have seen, an explicit analytic solution to the filtering problem can be obtained only for special models so that, remaining within analytic solutions, in general, one has to use an approximation approach. As already mentioned, one such approximation consists in linearizing the nonlinear model, both in discrete and continuous time, and this leads to the extended Kalman filter. Another approach consists in approximating the original model by one where x_t is finite-state Markov. The latter approach goes back mainly to Kushner and coworkers; see, for example, [18] (for a financial application, see also [13]). A more direct numerical approach is simulation-based and given by the so-called *particle approach to filtering* that has been successfully introduced more recently and that is summarized next.

Simulation-based Solution (Particle Filters).

Being simulation-based, this solution method as such is applicable only to discrete time models; continuous time models have to be first discretized in time. There are various variants of particle filters but, analogous to the analytical approaches, they all proceed along two steps, a prediction step and an updating step, and

at each step the relevant distribution (predictive and filter distribution, respectively) is approximated by a discrete probability measure supported by a finite number of points. These approaches vary mainly in the updating step.

A simple version of a particle filter is as follows (see [3]): in the generic period $t - 1$ approximate $p(x_{t-1} | y_0^{t-1})$ by a discrete distribution $((x_{t-1}^1, p_{t-1}^1), \dots, (x_{t-1}^L, p_{t-1}^L))$ where p_{t-1}^i is the probability that $x_{t-1} = x_{t-1}^i$. Consider each location x_{t-1}^i as the position of a “particle”.

1. Prediction step

Propagate each of the particles $x_{t-1}^i \rightarrow \hat{x}_t^i$ over one time period, using the given (discrete time) evolution dynamics of x_t : referring to the model in equation (2) just simulate independent trajectories of x_t starting from the various x_{t-1}^i . This leads to an approximation of $p(x_t | y_0^{t-1})$ by the discrete distribution $((\hat{x}_t^1, \hat{p}_t^1), \dots, (\hat{x}_t^L, \hat{p}_t^L))$ where one puts $\hat{p}_t^i = p_{t-1}^i$.

2. Updating step

Update the weights using the new observation y_t by putting $p_t^i = c p_{t-1}^i p(y_t | \hat{x}_t^i)$ where c is the normalization constant (see the second relation in equation (5) for an analogy).

Notice that $p(y_t | \hat{x}_t^i)$ may be viewed as the likelihood of particle $\hat{x}_t^i$, given the observation y_t , so that in the updating step one weighs each particle according to its likelihood. There exist various improvements of this basic setup. There are also variants, where in the updating step each particle is made to branch into a random number of offsprings, where the mean number of offsprings is taken to be proportional to the likelihood of that position. In this latter variant, the number of particles increases and one can show that, under certain assumptions, the empirical distribution of the particles converges to the true filter distribution. There is a vast literature on particle filters, of which we mention [5] and, in particular, [1].

Filtering in Finance

There are various situations in finance where filtering problems may arise, but one typical situation is given by factor models. These models have proven to be useful for capturing the complicated nonlinear dynamics of real asset prices, while at the same time being parsimonious and numerically tractable. In

addition, with Markovian factor processes, Markov-process techniques can be fruitfully applied. In many financial applications of factor models, the investors have only incomplete information about the actual state of the factors and this may induce model risk. In fact, even if the factors are associated with economic quantities, some of them are difficult to observe precisely. Furthermore, abstract factors without economic interpretation are often included in the specification of a model to increase its flexibility. Under incomplete information of the factors, their values have to be inferred from observable quantities and this is where filtering comes in as an appropriate tool.

Most financial problems concern pricing as well as portfolio management, in particular, hedging and portfolio optimization. While portfolio management is performed under the physical measure, for pricing, one has to use a martingale measure. Filtering problems in finance may therefore be considered under the physical or the martingale measures, or under both (see [22]). In what follows, we shall discuss filtering for pricing problems, with examples from term structure and credit risk, as well as for portfolio management. More general aspects can be found, for example, in the recent papers [6, 7], and [23].

Filtering in Pricing Problems

This section is to a large extent based on [14]. In Markovian factor models, the price of an asset at a generic time t can, under full observation of the factors, be expressed as an instantaneous function $\Psi(t, x_t)$ of time and the value of the factors. Let $\mathcal{G}_t$ denote the full filtration that measures all the processes of interest, and let $\mathcal{F}_t \subset \mathcal{G}_t$ be a subfiltration representing the information of an investor. What is an arbitrage-free price in the filtration $\mathcal{F}_t$? Assume the asset to be priced is a European derivative with maturity T and claim $H \in \mathcal{F}_T$. Let N be a numeraire, adapted to the investor filtration $\mathcal{F}_t$, and let Q^N be the corresponding martingale measure. One can easily prove the following:

Lemma 1 *Let $\Psi(t, x_t) = N_t E^{Q^N} \left\{ \frac{H}{N_T} \mid \mathcal{G}_t \right\}$ be the arbitrage-free price of the claim H under the full*

information $\mathcal{G}_t$ and $\hat{\Psi}(t) = N_t E^{Q^N} \left\{ \frac{H}{N_t} \mid \mathcal{F}_t \right\}$ the corresponding arbitrage-free price in the investor filtration. It then follows that

$$\hat{\Psi}(t) = E^{Q^N} \{ \Psi(t, x_t) \mid \mathcal{F}_t \} \quad (16)$$

Furthermore, if the savings account $B_t = \exp\{\int_0^t r_s ds\}$ with corresponding martingale measure Q is $\mathcal{F}_t$ -adapted, then

$$\hat{\Psi}(t) = E^Q \{ \Psi(t, x_t) \mid \mathcal{F}_t \} \quad (17)$$

We thus see that, to compute the right-hand sides in equation (16) or equation (17), namely, the price of a derivative under restricted information given its price under full information, one has to solve the filtering problem for x_t given $\mathcal{F}_t$ under a martingale measure. We present now two examples.

Example 1 (*Term structure of interests*). The example is a simplified version adapted from [15]. Consider a factor model for the term structure where the unobserved (multivariate) factor process x_t satisfies the linear-Gaussian model

$$dx_t = F x_t dt + D dw_t \quad (18)$$

In this case, the term structure is exponentially affine in x_t and one has

$$p(t, T; x_t) = \exp[A(t, T) - B(t, T) x_t] \quad (19)$$

with $A(t, T)$, $B(t, T)$ satisfying well-known first-order ordinary differential equations to exclude arbitrage. Passing to log-prices for the bonds, one gets the linear relationship $y_t^T := \log p(t, T; x_t) = A(t, T) - B(t, T) x_t$. Assume now that investors cannot observe x_t , but they can observe the short rate and the log-prices of a finite number n of zero-coupon bonds, perturbed by additive noise. This leads to a system of the form

$$\begin{cases} dx_t = F x_t dt + D dw_t \\ dr_t = (\alpha_t^0 + \beta_t^0 x_t) dt + \sigma_t^0 dw_t + dv_t^0 \\ dy_t^i = (\alpha_t^i + \beta_t^i x_t) dt + \sigma_t^i dw_t + (T_i - t) dv_t^i \\ \quad ; i = 1, \dots, n \end{cases} \quad (20)$$

where v_t^i , $i = 0, \dots, n$ are independent Wiener processes and the coefficients are related to those in equations (18) and (19). The time-dependent volatility in the perturbations of the log-prices reflects the fact that it tends to zero as time approaches maturity.

From the filtering point of view, the system (20) is a linear-Gaussian model with x_t unobserved and the observations given by (r_t, y_t^i) . We shall thus put $\mathcal{F}_t = \sigma\{r_s, y_s^i; s \leq t, i = 1, \dots, n\}$. The filter distribution is Gaussian and, via the Kalman filter, one can obtain its conditional mean m_t and (co)variance Σ_t . Applying Lemma 1 and using the moment-generating function of a Gaussian random variable, we obtain the arbitrage-free price, in the investor filtration, of an illiquid bond with maturity T as follows:

$$\begin{aligned} \hat{p}(t, T) &= E\{p(t, T; x_t) \mid \mathcal{F}_t\} \\ &= \exp[A(t, T)] E\{\exp[-B(t, T) x_t] \mid \mathcal{F}_t\} \\ &= \exp[A(t, T) - B(t, T) m_t] \\ &\quad + \frac{1}{2} B(t, T) \Sigma_t B'(t, T) \end{aligned} \quad (21)$$

For the given setup, the expectation is under the martingale measure Q with the money market account B_t as numeraire. To apply Lemma 1, we need the numeraire to be observable and this contrasts with the assumption that r_t is observable only in noise. This difficulty can be overcome (see [14]), but by suitably changing the drifts in equation (20) (corresponding to a translation of w_t), one may however consider the model in equation (20) also under a martingale measure for which the numeraire is different from B_t and observable.

A further filter application to the term structure of interest rates can be found in [2].

Example 2 (*Credit risk*). One of the main issues in credit risk is the modeling of the dynamic evolution of the default state of a given portfolio. To formalize the problem, given a portfolio of m obligors, let $y_t := (y_{t,1}, \dots, y_{t,m})$ be the default indicator process where $y_{t,i} := \mathbf{1}_{\{\tau_i \leq t\}}$ with τ_i the random default time of obligor i , $i = 1, \dots, m$. In line with the factor modeling philosophy, it is natural to assume that default intensities depend on an unobservable latent process x_t . In particular, if $\lambda_i(t)$ is the default intensity of obligor i , $i = 1, \dots, m$, assume $\lambda_i(t) = \lambda_i(x_t)$. Note that this generates *information-driven contagion*: it is, in fact, well known that the intensities with respect to $\mathcal{F}_t$ are given by $\hat{\lambda}_i(t) = E\{\lambda_i(x_t) \mid \mathcal{F}_t\}$. Hence the news that an obligor has defaulted leads, via filtering, to an update of the distribution

of x_t and thus to a jump in the default intensities of the still surviving obligors. In this context, we shall consider the pricing of illiquid credit derivatives on the basis of the investor filtration supposed to be given by the default history and noisily observed prices of liquid credit derivatives.

We assume that, conditionally on x_t , the defaults are independent with intensities $\lambda_i(x_t)$ and that (x_t, y_t) is jointly Markov. A credit derivative has the payoff linked to default events in a given reference portfolio and so one can think of it as a random variable $H \in \mathcal{F}_T^y$ with T being the maturity. Its full information price at the generic $t \leq T$, that is, in the filtration $\mathcal{G}_t$ that measures also x_t , is given by $\tilde{H}_t = E\{e^{-r(T-t)} H \mid \mathcal{G}_t\}$ where r is the short rate and the expectation is under a given martingale measure Q . By the Markov property of (x_t, y_t) , one gets a representation of the form

$$\tilde{H}_t = E\{e^{-r(T-t)} H \mid \mathcal{G}_t\} := a(t, x_t, y_t) \quad (22)$$

for a suitable $a(\cdot)$. In addition to the default history, we assume that the investor filtration also includes noisy observations of liquid credit derivatives. In view of equation (22), it is reasonable to model such observations as

$$dz_t = \gamma(t, x_t, y_t) dt + d\beta_t \quad (23)$$

where the various quantities may also be column vectors, β_t is an independent Wiener process and $\gamma(\cdot)$ is a function of the type of $a(\cdot)$ in equation (22). The investor filtration is then $\mathcal{F}_t = \mathcal{F}_t^y \vee \mathcal{F}_t^z$. The price at $t < T$ of the credit derivative in the investor filtration is now $H_t = E\{e^{-r(T-t)} H \mid \mathcal{F}_t\}$ and by Lemma 1 we have

$$H_t = E\{e^{-r(T-t)} H \mid \mathcal{F}_t\} = E\{a(t, x_t, y_t) \mid \mathcal{F}_t\} \quad (24)$$

Again, if one knows the price $a(t, x_t, y_t)$ in $\mathcal{G}_t$, one can thus obtain the price in $\mathcal{F}_t$ by computing the right-hand side in equation (24) and for this we need the filter distribution of x_t given $\mathcal{F}_t$.

To define the corresponding filtering problem, we need a more precise model for (x_t, y_t) (the process z_t is already given by equation (23)). Since y_t is a jump process, the model cannot be one of those for which we had described an explicit analytic solution. Without entering into details, we refer to [13] (see also [14]), where a jump-diffusion model is considered that allows for common jumps between

x_t and y_t . In [13] it is shown that an arbitrarily good approximation to the filter solution can be obtained both analytically and by particle filtering.

We conclude this section with a couple of additional remarks:

1. Traditional credit risk models are either structural models or reduced-form (intensity-based) models. Example 2 belongs to the latter class. In *structural models*, the default of the generic obligor/firm i is defined as the first passage time of the asset value $V_i(t)$ of the firm at a given (possibly stochastic) barrier $K_i(t)$, that is,

$$\tau_i = \inf\{t \geq 0 \mid V_i(t) \leq K_i(t)\} \quad (25)$$

In such a context, filtering problems may arise when either $V_i(t)$ or $K_i(t)$ or both are not exactly known/observable (see e.g., [9]).

2. *Can a structural model also be seen as a reduced-form model?* At first sight, this is not clear since τ_i in equation (25) is predictable, while in intensity-based models it is totally inaccessible. However, it turns out (see e.g., [16]) that, while τ_i in equation (25) is predictable with respect to the full filtration (measuring also $V_i(t)$ and $K_i(t)$), it becomes totally inaccessible in the smaller investor filtration that, say, does not measure $V_i(t)$ and, furthermore, it admits an intensity.

Filtering in Portfolio Management Problems

Rather than presenting a general treatment (for this, we refer to [21] and the references therein), we discuss here two specific examples in models with unobserved factors, one in discrete time and one in continuous time. Contrary to the previous section on pricing, here we shall work under the physical measure P .

A Discrete Time Case. To motivate the model, start from the classical continuous time asset price model $dS_t = S_t[a dt + x_t dw_t]$ where w_t is Wiener and x_t is the nondirectly observable volatility process (factor). For $y_t := \log S_t$, one then has

$$dy_t = \left(a - \frac{1}{2}x_t^2\right) dt + x_t dw_t \quad (26)$$

Passing to discrete time with step δ , let for $t = 0, \dots, T$ the process x_t be a Markov chain with m

states $x^1, \dots, x^m$ (may result from a time discretization of a continuous time x_t) and

$$y_t = y_{t-1} + \left(a - \frac{1}{2}x_{t-1}^2\right)\delta + x_{t-1}\sqrt{\delta}\varepsilon_t \quad (27)$$

with ε_t i.i.d. standard Gaussian as it results from equation (26) by applying the Euler–Maruyama scheme. Notice that (x_t, y_t) is Markov. Having for simplicity only one stock to invest in, denote by ϕ_t the number of shares of stock held in the portfolio in period t with the rest invested in a riskless bond B_t (for simplicity assume $r = 0$). The corresponding self-financed wealth process then evolves according to

$$V_{t+1}^\phi = V_t^\phi + \phi_t (e^{y_{t+1}} - e^{y_t}) := F(V_t^\phi, \phi_t, y_t, y_{t+1}) \quad (28)$$

and ϕ_t is supposed to be adapted to $\mathcal{F}_t^y$; denote by $\mathcal{A}$ the class of such strategies. Given a horizon T , consider the following investment criterion

$$\begin{aligned} J_{\text{opt}}(V_0) &= \sup_{\phi \in \mathcal{A}} J(V_0, \phi) \\ &= \sup_{\phi \in \mathcal{A}} E \left\{ \sum_{t=0}^{T-1} r_t(x_t, y_t, V_t^\phi, \phi_t) \right. \\ &\quad \left. + f(x_T, y_T, V_T^\phi) \right\} \end{aligned} \quad (29)$$

which, besides portfolio optimization, includes also hedging problems. The problem in equations (27), (28), and (29) is now a stochastic control problem under partial/incomplete information given that x_t is an unobservable factor process.

A standard approach to dynamic optimization problems under partial information is to transform them into corresponding complete information ones whereby x_t is replaced by its filter distribution given $\mathcal{F}_t^y$. Letting $\pi_t^i := P\{x_t = x^i \mid \mathcal{F}_t^y\}$, $i = 1, \dots, m$ we first adapt the filter dynamics in equation (5) to our situation to derive a recursive relation for $\pi_t = (\pi_t^1, \dots, \pi_t^m)$. Being x_t finite-state Markov, $p(x_{t+1} \mid x_t)$ is given by the transition probability matrix and the integral in equation (5) reduces to a sum. On the other hand, $p(y_t \mid x_t)$ in equation (5) corresponds to the model in equation (2) that does not include our model in equation (27) for y_t . One can however easily see that equation (27) leads to a

distribution of the form $p(y_t \mid x_{t-1}, y_{t-1})$, and equation (5) can be adapted to become here

$$\begin{cases} \pi_0 = \mu & \text{(initial distribution for } x_t) \\ \pi_t^i \propto \sum_{j=1}^m p(y_t \mid x_{t-1} = j, y_{t-1}) \\ \quad p(x_t = i \mid x_{t-1} = j) \pi_{t-1}^j \end{cases} \quad (30)$$

In addition, we may consider the law of y_t conditional on $(\pi_{t-1}, y_{t-1}) = (\pi, y)$ that is given by

$$\begin{aligned} Q_t(\pi, y, dy') &= \sum_{i,j=1}^m p(y' \mid x_{t-1} = j, y) \\ &\quad p(x_t = i \mid x_{t-1} = j) \pi^j \end{aligned} \quad (31)$$

From equations (30) and (31), it follows easily that (π_t, y_t) is a sufficient statistic and an $\mathcal{F}_t^y$ -Markov process.

To transform the original partial information problem with criterion (29) into a corresponding complete observation problem, put $\hat{r}_t(\pi, y, v, \phi) = \sum_{i=1}^m r_t(x^i, y, v, \phi) \pi^i$ and $\hat{f}(\pi, y, v) = \sum_{i=1}^m f(x^i, y, v) \pi^i$ so that, by double conditioning, one obtains

$$\begin{aligned} J(V_0, \phi) &= E \left\{ \sum_{t=0}^{T-1} E \left\{ r_t(x_t, y_t, V_t^\phi, \phi_t) \mid \mathcal{F}_t^y \right\} \right. \\ &\quad \left. + E \left\{ f(x_T, y_T, V_T^\phi) \mid \mathcal{F}_T^y \right\} \right\} \\ &= E \left\{ \sum_{t=0}^{T-1} \hat{r}_t(\pi_t, y_t, V_t^\phi, \phi_t) + \hat{f}(\pi_T, y_T, V_T^\phi) \right\} \end{aligned} \quad (32)$$

Owing to the Markov property of (π_t, y_t) , one can write the following (backward) dynamic programming recursions:

$$\begin{cases} u_T(\pi, y, v) = \hat{f}(\pi, y, v) \\ u_t(\pi, y, v) = \sup_{\phi \in \mathcal{A}} [\hat{r}_t(\pi, y, v, \phi) \\ \quad + E \{ u_{t+1}(\pi_{t+1}, y_{t+1}, \\ \quad F(v, \phi, y, y_{t+1})) \mid (\pi_t, y_t) = (\pi, y) \}] \end{cases} \quad (33)$$

where the function $F(\cdot)$ was defined in equation (28), and ϕ here refers to the generic choice of $\phi = \phi_t$ in period t . It leads to the optimal investment strategy ϕ^* and the optimal value $J_{\text{opt}}(V_0) = u_0(\mu, y_0, V_0)$. It can, in fact, be shown that the strategy and value thus

obtained are optimal also for the original incomplete information problem when ϕ there is required to be $\mathcal{F}_t^y$ -adapted.

To actually compute the recursions in equation (33), one needs the conditional law of (π_{t+1}, y_{t+1}) given (π_t, y_t) , which can be deduced from equations (30) and (31). In this context, notice that, even if x is m -valued, π_t takes values in the m -dimensional simplex that is ∞ -valued. To actually perform the calculation, one needs an approximation leading to a finite-valued process (π_t, y_t) and to this effect various approaches have appeared in the literature (for an approach with numerical results see [4]).

A Continuous Time Case. Consider the following market model where x_t is an unobserved factor process and S_t is the price of a single risky asset:

$$\begin{cases} dx_t = F_t(x_t) dt + R_t(x_t) dM_t \\ dS_t = S_t [a_t(S_t, x_t) dt + \sigma_t(S_t) dw_t] \end{cases} \quad (34)$$

with w_t a Wiener process and M_t a not necessarily continuous martingale, independent of w_t . Since, in continuous time, $\int_0^t \sigma_s^2 ds$ can be estimated by the empirical quadratic variation of S_t , in order not to have degeneracy in the filter to be derived below for x_t , we do not let $\sigma(\cdot)$ depend also on x_t . For the riskless asset, we assume for simplicity that its price is $B_t \equiv \text{const}$ (short rate $r = 0$). In what follows, it is convenient to consider log-prices $y_t = \log S_t$, for which

$$\begin{aligned} dy_t &= [a_t(S_t, x_t) - \frac{1}{2}\sigma_t^2(S_t)] dt + \sigma_t(S_t) dw_t \\ &:= A_t(y_t, x_t) dt + B_t(y_t) dw_t \end{aligned} \quad (35)$$

Investing in this market in a self-financing way and denoting by ρ_t the fraction of wealth invested in the risky asset, we have from $\frac{dV_t}{V_t} = \rho_t \frac{dS_t}{S_t} = \rho_t \frac{d}{e^{y_t}} e^{y_t}$ that

$$\begin{aligned} dV_t &= V_t \left[\rho_t \left(A_t(y_t, x_t) + \frac{1}{2} B_t^2(y_t) \right) dt \right. \\ &\quad \left. + \rho_t B_t(y_t) dw_t \right] \end{aligned} \quad (36)$$

We want to consider the problem of maximization of expected utility from terminal wealth, without

consumption, and with a power utility function. Combining equations (34), (35), and (36) we obtain the following portfolio optimization problem under incomplete information where the factor process x_t is not observed and where we shall require that ρ_t is $\mathcal{F}_t^y$ -adapted:

$$\begin{cases} dx_t = F_t(x_t) dt + R_t(x_t) dM_t & (\text{unobserved}) \\ dy_t = A_t(y_t, x_t) dt + B_t(y_t) dw_t & (\text{observed}) \\ dV_t = V_t \left[\rho_t \left(A_t(y_t, x_t) + \frac{1}{2} B_t^2(y_t) \right) dt \right. \\ \quad \left. + \rho_t B_t(y_t) dw_t \right] \\ \sup_{\rho} E \{ (V_T)^\mu \}, \quad \mu \in (0, 1) \end{cases} \quad (37)$$

As in the previous discrete time case, we shall now transform this problem into a corresponding one under complete information, thereby replacing the unobserved state variable x_t by its filter distribution, given $\mathcal{F}_t^y$, that is, $\pi_t(x) := p(x_t | \mathcal{F}_t^y)_{x_t=x}$. Even if x_t is finite-dimensional, $\pi_t(\cdot)$ is ∞ -dimensional. We have seen above cases where the filter distribution is finitely parameterized, namely, the linear-Gaussian case (*Kalman filter*) and when x_t is finite-state Markov. The parameters characterizing the filter were seen to evolve over time driven by the innovations process (see equations (8), (10) and (14)). In what follows, we then assume that the filter is parameterized by a vector process $\xi_t \in \mathbb{R}^p$, that is, $\pi_t(x) := p(x_t | \mathcal{F}_t^y)_{x_t=x} = \pi(x; \xi_t)$ and that ξ_t satisfies

$$d\xi_t = \beta_t(y_t, \xi_t) dt + \eta_t(y_t, \xi_t) d\bar{w}_t \quad (38)$$

where $\bar{w}_t$ is Wiener and given by the innovations process. We now specify this innovations process $\bar{w}_t$ for our general model in equation (37). To this effect, putting $A_t(y_t, \xi_t) := \int A_t(y_t, x) d\pi_t(x; \xi_t)$, let

$$d\bar{w}_t := B_t^{-1}(y_t) [dy_t - A_t(y_t, \xi_t) dt] \quad (39)$$

and notice that, replacing dy_t from equation (35), this definition implies a translation of the original $(P, \mathcal{F}_t)$ -Wiener w_t , that is,

$$d\bar{w}_t = dw_t + B_t^{-1}(y_t) [A_t(y_t, x_t) - A_t(y_t, \xi_t)] dt \quad (40)$$

and thus the implicit change of measure $P \rightarrow \bar{P}$ with

$$\begin{aligned} \frac{d\bar{P}}{dP}|_{\mathcal{F}_T} = \exp \left\{ \int_0^T [A_t(y_t, \xi_t) - A_t(y_t, x_t)] \right. \\ \left. \times B_t^{-1}(y_t) dw_t - \frac{1}{2} \int_0^T [A_t(y_t, \xi_t) \right. \\ \left. - A_t(y_t, x_t)]^2 B_t^{-2}(y_t) dt \right\} \quad (41) \end{aligned}$$

We obtain thus as the complete information problem corresponding to equation (37), the following, which is defined on the space $(\Omega, \mathcal{F}, \mathcal{F}_t, \bar{P})$ with Wiener $\bar{w}_t$:

$$\begin{cases} d\xi_t = \beta_t(y_t, \xi_t) dt + \eta_t(y_t, \xi_t) d\bar{w}_t \\ dy_t = A_t(y_t, \xi_t) dt + B_t(y_t) d\bar{w}_t \\ dV_t = V_t \left[\rho_t \left(A_t(y_t, \xi_t) + \frac{1}{2} B_t^2(y_t) \right) dt \right. \\ \left. + \rho_t B_t(y_t) d\bar{w}_t \right] \\ \sup_{\rho} \bar{E} \{ (V_T)^\mu \}, \quad \mu \in (0, 1) \end{cases} \quad (42)$$

One can now use methods for complete information problems to solve equation (42), and it can also be shown that the solution to equation (42) gives a solution of the original problem for which ρ_t was assumed $\mathcal{F}_t^y$ -adapted.

We remark that other reformulations of the incomplete information problem as a complete information one are also possible (see e.g., [20]).

A final comment concerns hedging under incomplete information (incomplete market). When using the quadratic hedging criterion, that is, $\min_{\rho} E_{S_0, V_0} \{(H_T - V_T^\rho)^2\}$, its quadratic nature implies that if $\phi_t^*(x_t, y_t)$ is the optimal strategy (number of units invested in the risky asset) under complete information also of x_t , then, under the partial information $\mathcal{F}_t^y$, the optimal strategy is simply the projection $E\{\phi_t^*(x_t, y_t) | \mathcal{F}_t^y\}$ that can be computed on the basis of the filter of x_t given $\mathcal{F}_t^y$ (see [12]).

Filtrations

The notion of *filtration*, introduced by Doob, has become a fundamental feature of the theory of stochastic processes. Most basic objects, such as martingales, semimartingales, stopping times, or Markov processes, involve the notion of filtration.

Definition 1 Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space. A filtration $\mathbb{F}$, on $(\Omega, \mathcal{F}, \mathbb{P})$, is an increasing family $(\mathcal{F}_t)_{t \geq 0}$ of sub- σ -algebras of $\mathcal{F}$. In other words, for each t , $\mathcal{F}_t$ is a σ -algebra included in $\mathcal{F}$ and if $s \leq t$, $\mathcal{F}_s \subset \mathcal{F}_t$. A probability space $(\Omega, \mathcal{F}, \mathbb{P})$ endowed with a filtration $\mathbb{F}$ is called a *filtered probability space*.

We now give a definition that is very closely related to that of a filtration.

Definition 2 A stochastic process $(X_t)_{t \geq 0}$ on $(\Omega, \mathcal{F}, \mathbb{P})$ is adapted to the filtration $(\mathcal{F}_t)$ if, for each $t \geq 0$, X_t is $\mathcal{F}_t$ -measurable.

A stochastic process X is always adapted to its *natural filtration* $\mathbb{F}^X$, where for each $t \geq 0$, $\mathcal{F}_t^X = \sigma(X_s, s \leq t)$ (the last notation means that $\mathcal{F}_t$ is the smallest σ -algebra with respect to which all the variables $(X_s, s \leq t)$ are measurable). $\mathbb{F}^X$ is, hence, the smallest filtration to which X is adapted.

The parameter t is often thought of as time, and the σ -algebra $\mathcal{F}_t$ represents the set of information available at time t , that is, events that have occurred up to time t . Thus, the filtration $\mathbb{F}$ represents the evolution of the information or knowledge of the world with time. If X is an adapted process, then X_t , its value at time t , depends only on the evolution of the universe prior to t .

Definition 3 Let $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ be a filtered probability space.

1. The filtration $\mathbb{F}$ is said to be *complete* if $(\Omega, \mathcal{F}, \mathbb{P})$ is complete and if $\mathcal{F}_0$ contains all the $\mathbb{P}$ -null sets.
2. The filtration $\mathbb{F}$ is said to satisfy the *usual hypotheses* if it is complete and right continuous, that is, for all $t \geq 0$, $\mathcal{F}_t = \mathcal{F}_{t+}$, where

$$\mathcal{F}_{t+} = \bigcap_{u > t} \mathcal{F}_u \quad (1)$$

Some fundamental theorems, such as the D  but theorem, require the usual hypotheses. Hence naturally, very often in the literature on the theory of stochastic processes and mathematical finance, the underlying filtered probability spaces are assumed to satisfy the usual hypotheses. This assumption is not very restrictive for the following reasons:

1. Any filtration can easily be made complete and right continuous; indeed, given a filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$, we first complete the probability space $(\Omega, \mathcal{F}, \mathbb{P})$, and then we add all the $\mathbb{P}$ -null sets to every $\mathcal{F}_{t+}$, $t \geq 0$. The new filtration thus obtained satisfies the usual hypotheses and is called the *usual augmentation* of $\mathbb{F}$;
2. Moreover, in most classical and encountered cases, the filtration $\mathbb{F}$ is right continuous. Indeed, this is the case when, for instance, $\mathbb{F}$ is the natural filtration of a Brownian motion, a L  vy process, a Feller process, or a Hunt process [8, 9].

For more precise and detailed references, the reader can consult the books [4–6, 8] or the survey article [7].

Generalities

Let $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ be a filtered probability space satisfying the usual hypotheses. Let $\mathbb{G}$ be another filtration satisfying the usual hypotheses and such that $\mathcal{F}_t \subset \mathcal{G}_t$ for every $t \geq 0$. One natural question is, how are the $\mathbb{F}$ -semimartingales modified when considered as stochastic processes in the larger filtration $\mathbb{G}$? Given the importance of semimartingales and martingales (in particular, in mathematical finance where they are used to model prices), it seems natural to characterize situations where the semimartingale or martingale properties are preserved.

Definition 4 We shall say that the pair of filtrations $(\mathbb{F}, \mathbb{G})$ satisfies the *(H') hypothesis* if every $\mathbb{F}$ -semimartingale is a $\mathbb{G}$ -semimartingale.

Remark 1 In fact, using a classical decomposition of semimartingales due to Jacod and M  min, it is enough to check that every $\mathbb{F}$ -bounded martingale is a $\mathbb{G}$ -semimartingale.

Definition 5 We shall say that the pair of filtrations $(\mathbb{F}, \mathbb{G})$ satisfies the (H) hypothesis if every $\mathbb{F}$ -local martingale is a $\mathbb{G}$ -local martingale.

The theory of enlargements of filtrations, developed in the late 1970s, provides answers to questions such as those mentioned earlier. Currently, this theory has been widely used in mathematical finance, especially in insider trading models and in models of default risk. The insider trading models are usually based on the so-called *initial enlargements of filtrations*, whereas the models of default risk fit well in the framework of the *progressive enlargements of filtrations*. More precisely, given a filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$, there are essentially two ways of enlarging filtrations:

- *initial enlargements*, for which $\mathcal{G}_t = \mathcal{F}_t \vee \mathcal{H}$ for every $t \geq 0$, that is, the new information $\mathcal{H}$ is brought in at the origin of time and
- *progressive enlargements*, for which $\mathcal{G}_t = \mathcal{F}_t \vee \mathcal{H}_t$ for every $t \geq 0$, that is, the new information is brought in progressively as the time t increases.

Before presenting the basic theorems on enlargements of filtrations, we state a useful theorem due to Stricker.

Theorem 1 (Stricker [10]). Let $\mathbb{F}$ and $\mathbb{G}$ be two filtrations as above, such that for all $t \geq 0$, $\mathcal{F}_t \subset \mathcal{G}_t$. If (X_t) is a $\mathbb{G}$ -semimartingale that is $\mathbb{F}$ -adapted, then it is also an $\mathbb{F}$ -semimartingale.

Initial Enlargements of Filtrations

The most important theorem on initial enlargements of filtrations is due to Jacod and deals with the special case where the initial information brought in at the origin of time consists of the σ -algebra generated by a random variable. More precisely, let $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ be a filtered probability space satisfying the usual assumptions. Let Z be an $\mathcal{F}$ measurable random variable. Define

$$\mathcal{G}_t = \bigcap_{\varepsilon > 0} \left(\mathcal{F}_{t+\varepsilon} \vee \sigma\{Z\} \right), \quad t \geq 0 \quad (2)$$

In financial models, the filtration $\mathbb{F}$ represents the public information in a financial market and the random variable Z stands for the additional (anticipating) information of an insider.

The conditional laws of Z given $\mathcal{F}_t$, for $t \geq 0$, play a crucial role in initial enlargements.

Theorem 2 (Jacod's criterion). Let Z be an $\mathcal{F}$ measurable random variable and let $Q_t(\omega, dx)$ denote the regular conditional distribution of Z given $\mathcal{F}_t$, $t \geq 0$. Suppose that for each $t \geq 0$, there exists a positive σ -finite measure $\eta_t(dx)$ (on $(\mathbb{R}, \mathcal{B}(\mathbb{R}))$) such that

$$Q_t(\omega, dx) \ll \eta_t(dx) \text{ almost surely} \quad (3)$$

Then every $\mathbb{F}$ -semimartingale is a $\mathbb{G}$ -semimartingale.

Remark 2 In fact, this theorem still holds for random variables with values in a standard Borel space. Moreover, the existence of the σ -finite measure $\eta_t(dx)$ is equivalent to the existence of one positive σ -finite measure $\eta(dx)$ such that $Q_t(\omega, dx) \ll \eta(dx)$ and in this case η can be taken to be the distribution of Z .

Now we give classical corollaries of Jacod's theorem.

Corollary 1 Let Z be independent of $\mathcal{F}_\infty$. Then, every $\mathbb{F}$ -semimartingale is a $\mathbb{G}$ -semimartingale.

Corollary 2 Let Z be a random variable taking on only a countable number of values. Then every $\mathbb{F}$ -semimartingale is a $\mathbb{G}$ -semimartingale.

In some cases, it is possible to obtain an explicit decomposition of an $\mathbb{F}$ -local martingale as a $\mathbb{G}$ -semimartingale [4–8]. For example, if $Z = B_{t_0}$, for some fixed time $t_0 > 0$ and a Brownian Motion B , it can be shown that Jacod's criterion holds for $t < t_0$ and that every $\mathbb{F}$ -local martingale is a semimartingale for $0 \leq t < t_0$, but not necessarily including t_0 . Indeed in this case, there are $\mathbb{F}$ -local martingales that are not $\mathbb{G}$ -semimartingales. Moreover, B is a $\mathbb{G}$ -semimartingale, which decomposes as

$$B_t = B_0 + \tilde{B}_t + \int_0^{t \wedge t_0} ds \frac{B_{t_0} - B_s}{t_0 - s} \quad (4)$$

where $(\tilde{B}_t)$ is a $\mathbb{G}$ Brownian Motion.

Remark 3 There are cases where Jacod's criterion does not hold but where other methods apply [4, 6, 7].

Progressive Enlargements of Filtrations

Let $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ be a filtered probability space satisfying the usual hypotheses, and $\rho : (\Omega, \mathcal{F}) \rightarrow (\mathbb{R}_+, \mathcal{B}(\mathbb{R}_+))$ be a random time. We enlarge the initial filtration $\mathbb{F}$ with the process $(\rho \wedge t)_{t \geq 0}$, so that the new enlarged filtration $\mathbb{F}^\rho$ is the smallest filtration (satisfying the usual assumptions) containing $\mathbb{F}$ and making ρ a stopping time (i.e., for all $t \geq 0$, $\mathcal{F}_t^\rho = \mathcal{K}_{t+}^\rho$, where $\mathcal{K}_t^\rho = \mathcal{F}_t \vee \sigma(\rho \wedge t)$). One may interpret ρ as the instant of default of an issuer; the given filtration $\mathbb{F}$ can be thought of as the filtration of default-free prices, for which ρ is not a stopping time. Then, the filtration $\mathbb{F}^\rho$ is the defaultable market filtration used for the pricing of defaultable assets.

A few processes play a crucial role in our discussion:

- the $\mathbb{F}$ -supermartingale

$$Z_t^\rho = \mathbb{P}[\rho > t \mid \mathcal{F}_t] \quad (5)$$

chosen to be càdlàg, associated to ρ by Azéma [1];

- the $\mathbb{F}$ -dual optional projection of the process $\mathbf{1}_{\{\rho \leq t\}}$, denoted by A_t^ρ (see [7, 8] for a definition of dual optional projections); and
- the càdlàg martingale

$$\mu_t^\rho = \mathbb{E}[A_\infty^\rho \mid \mathcal{F}_t] = A_t^\rho + Z_t^\rho \quad (6)$$

Theorem 3 Every $\mathbb{F}$ -local martingale (M_t) , stopped at ρ , is an $\mathbb{F}^\rho$ -semimartingale, with canonical decomposition:

$$M_{t \wedge \rho} = \tilde{M}_t + \int_0^{t \wedge \rho} \frac{d\langle M, \mu^\rho \rangle_s}{Z_{s-}^\rho} \quad (7)$$

where $(\tilde{M}_t)$ is an $\mathbb{F}^\rho$ -local martingale.

The most interesting case in the theory of progressive enlargements of filtrations is when ρ is an *honest time* or equivalently the end of an $\mathbb{F}$ optional set Γ , that is,

$$\rho = \sup\{t : (t, \omega) \in \Gamma\} \quad (8)$$

Indeed, in this case, the pair of filtrations $(\mathbb{F}, \mathbb{F}^\rho)$ satisfies the (H') hypothesis: every $\mathbb{F}$ -local martingale (M_t) is an $\mathbb{F}^\rho$ -semimartingale, with canonical decomposition:

$$M_t = \tilde{M}_t + \int_0^{t \wedge \rho} \frac{d\langle M, \mu^\rho \rangle_s}{Z_{s-}^\rho} - \int_\rho^t \mathbf{1}_{\{\rho \leq t\}} \frac{d\langle M, \mu^\rho \rangle_s}{1 - Z_{s-}^\rho} \quad (9)$$

The next decomposition formulas are used for pricing in default models:

Proposition 1

1. Let $\xi \in L^1$. Then a càdlàg version of the martingale $\xi_t = \mathbb{E}[\xi \mid \mathcal{F}_t^\rho]$, on the set $\{t < \rho\}$, is given by:

$$\xi_t \mathbf{1}_{t < \rho} = \frac{1}{Z_t^\rho} \mathbf{1}_{t < \rho} \mathbb{E}[\xi \mathbf{1}_{t < \rho} \mid \mathcal{F}_t] \quad (10)$$

2. Let $\xi \in L^1$ and let ρ be an honest time. Then a càdlàg version of the martingale $\xi_t = \mathbb{E}[\xi \mid \mathcal{F}_t^\rho]$ is given as

$$\begin{aligned} \xi_t &= \frac{1}{Z_t^\rho} \mathbb{E}[\xi \mathbf{1}_{t < \rho} \mid \mathcal{F}_t] \mathbf{1}_{t < \rho} \\ &\quad + \frac{1}{1 - Z_t^\rho} \mathbb{E}[\xi \mathbf{1}_{t \geq \rho} \mid \mathcal{F}_t] \mathbf{1}_{t \geq \rho} \end{aligned} \quad (11)$$

The (H) Hypothesis

The (H) hypothesis, in contrast to the (H') hypothesis, is sometimes presented as a no-arbitrage condition in default models. Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space satisfying the usual assumptions. Let $\mathbb{F}$ and $\mathbb{G}$ be two subfiltrations of $\mathcal{F}$, with

$$\mathcal{F}_t \subset \mathcal{G}_t \quad (12)$$

Brémaud and Yor [2] have proven the following characterization of the (H) hypothesis:

Theorem 4 The following are equivalent:

1. Every $\mathbb{F}$ -martingale is a $\mathbb{G}$ -martingale.
2. For all $t \geq 0$, the sigma fields $\mathcal{G}_t$ and $\mathcal{F}_\infty$ are independent conditionally on $\mathcal{F}_t$.

Remark 4 We also say that $\mathbb{F}$ is *immersed* in $\mathbb{G}$.

In the framework of the progressive enlargement of some filtration $\mathbb{F}$ with a random time ρ , the (H) hypothesis is equivalent to one of the following hypothesis [3]:

1. $\forall t$, the σ -algebras $\mathcal{F}_\infty$ and $\mathcal{F}_t^\rho$ are conditionally independent given $\mathcal{F}_t$.
2. For all bounded $\mathcal{F}_\infty$ measurable random variables $\mathbf{F}$ and all bounded $\mathcal{F}_t^\rho$ measurable random variables $\mathbf{G}_t$, we have

$$\mathbb{E}[\mathbf{F} \mathbf{G}_t \mid \mathcal{F}_t] = \mathbb{E}[\mathbf{F} \mid \mathcal{F}_t] \mathbb{E}[\mathbf{G}_t \mid \mathcal{F}_t] \quad (13)$$

3. For all bounded $\mathcal{F}_t^o$ measurable random variables $\mathbf{G}_t$:

$$\mathbb{E}[\mathbf{G}_t \mid \mathcal{F}_\infty] = \mathbb{E}[\mathbf{G}_t \mid \mathcal{F}_t] \quad (14)$$

4. For all bounded $\mathcal{F}_\infty$ measurable random variables $\mathbf{F}$,

$$\mathbb{E}[\mathbf{F} \mid \mathcal{F}_t^o] = \mathbb{E}[\mathbf{F} \mid \mathcal{F}_t] \quad (15)$$

5. For all $s \leq t$,

$$\mathbb{P}[\rho \leq s \mid \mathcal{F}_t] = \mathbb{P}[\rho \leq s \mid \mathcal{F}_\infty] \quad (16)$$

In view of applications to financial mathematics, a natural question is, how is the (H) hypothesis affected when we make an equivalent change of probability measure?

Proposition 2 *Let $\mathbb{Q}$ be a probability measure that is equivalent to $\mathbb{P}$ (on $\mathcal{F}$). Then, every $(\mathbb{F}, \mathbb{Q})$ -semimartingale is a $(\mathbb{G}, \mathbb{Q})$ -semimartingale.*

Now, define

$$\frac{d\mathbb{Q}}{d\mathbb{P}} \Big|_{\mathcal{F}_t} = R_t, \quad \frac{d\mathbb{Q}}{d\mathbb{P}} \Big|_{\mathcal{G}_t} = R'_t \quad (17)$$

If $Y = \frac{d\mathbb{Q}}{d\mathbb{P}}$, then the hypothesis (H) holds under $\mathbb{Q}$ if and only if

$$\forall X \geq 0, \quad X \in \mathcal{F}_\infty, \quad \frac{\mathbb{E}_{\mathbb{P}}[XY \mid \mathcal{G}_t]}{R'_t} = \frac{\mathbb{E}_{\mathbb{P}}[XY \mid \mathcal{F}_t]}{R_t} \quad (18)$$

In particular, when $\frac{d\mathbb{Q}}{d\mathbb{P}}$ is $\mathcal{F}_\infty$ measurable, $R_t = R'_t$ and the hypothesis (H) holds under $\mathbb{Q}$.

A decomposition formula is given below.

Theorem 5 *If (X_t) is a $(\mathbb{F}, \mathbb{Q})$ -local martingale, then the stochastic process*

$$I_X(t) = X_t + \int_0^t \frac{R'_{s-}}{R'_s}$$

$$\times \left(\frac{1}{R_{s-}} d[X, R]_s - \frac{1}{R'_{s-}} d[X, R']_s \right) \quad (19)$$

is a $(\mathbb{G}, \mathbb{Q})$ -local martingale.

Local Times

The most obvious way to measure the time that a random process X spends at a value b on a time interval $[0, t]$ is to compute $\int_0^t 1_{\{X_s=b\}} ds$. The problem is that this expression might be equal to 0, although the process X actually visits the value b . This is realized by the real Brownian motion (for a definition of this process, see **Lévy Processes**). Indeed, if we denote this process B , then for every fixed real b the set $\{s \geq 0 : B_s = b\}$ has 0 Lebesgue measure and is infinite (and uncountable). However, one can measure the time that B spends at b by using the notion of *local time* defined by

$$L_t^b = \lim_{\epsilon \rightarrow 0} \frac{1}{2\epsilon} \int_0^t 1_{\{|B_s - b| < \epsilon\}} ds \quad (1)$$

where the limit is a pathwise limit.

For a fixed b , the process $(L_t^b, t \geq 0)$ is an increasing process that only increases at times when B takes the value b . Under the assumption that B starts at 0, the processes $(L_t^0, t \geq 0)$ and $(2 \sup_{0 \leq s \leq t} B_s, s \geq 0)$ have the same law. This identity is due to Paul Lévy.

As b varies and t is fixed, one obtains the process $(L_t^b, b \in \mathbb{R})$, which actually represents the density of occupation time of B during the time interval $[0, t]$. This fact corresponds to the following formula called the *occupation time formula*

$$\int_0^t f(B_s) ds = \int_{\mathbb{R}} f(b) L_t^b db \quad (2)$$

for every measurable bounded function f . This formula provides a definition of the local time equivalent to definition (1). For a fixed t , one does not know, special times excepted, the law of the process $(L_t^b, b \in \mathbb{R})$, but a lot of trajectorial results are established. For example, from [6], we have

$$\liminf_{t \rightarrow \infty} \sup_{x \in \mathbb{R}} L_t^x (t^{-1} \log \log t)^{1/2} = c \quad (3)$$

with $0 < c < \infty$, and

$$\limsup_{t \rightarrow \infty} \sup_{x \in \mathbb{R}} L_t^x (t \log \log t)^{-1/2} = \sqrt{2} \quad (4)$$

One of these special times is T_a , the first hitting time by B of a given value a . The law of $(L_{T_a}^b, b \in \mathbb{R})$ is described by one of the famous *Ray–Knight Theorems* (see [8, Chapter XI]).

The local time of B can also be considered as a doubly indexed process. As such it is a.s. jointly continuous in b and t (see [9]) and deterministic functions on $\mathbb{R} \times \mathbb{R}_+$ can be integrated with respect to $(L_t^b, b \in \mathbb{R}, t \geq 0)$ (see **Itô's Formula**).

Local Time of a Semimartingale

Similarly to formula (2), one can define the local time process of a semimartingale Y (for the definition of a semimartingale, see **Stochastic Integrals**) by using the following occupation time formula:

$$\int_0^t f(Y_s) d[Y]_s^c = \int_{\mathbb{R}} f(b) L_t^b(Y) db \quad (5)$$

where $([Y]_s^c, s \geq 0)$ is the continuous part of the quadratic variation of Y also denoted by $\langle Y \rangle$ (for the definition see **Stochastic Integrals**). For a fixed b $(L_t^b(Y), t \geq 0)$ is a.s. continuous.

The obtained local time process $(L_t^b(Y), b \in \mathbb{R}, t \geq 0)$ satisfies the following formula, called *Tanaka's formula*:

$$\begin{aligned} |Y_t - b| &= |Y_0 - b| + \int_0^t \text{sgn}(Y_s - b) dY_s + L_t^b \\ &+ \sum_{0 < s \leq t} \{|Y_s - b| - |Y_{s-} - b| - \text{sgn}(Y_{s-} - b) \Delta Y_s\} \end{aligned} \quad (6)$$

where the function sgn is defined by $\text{sgn}(x) = 1_{x>0} - 1_{x \leq 0}$. Tanaka's formula actually provides a definition of the local time equivalent to formula (5). Thanks to this formula, Paul Lévy's identity is extended in [5] to the continuous semimartingales starting from 0 under the form

$$(L_t^0, t \geq 0) \stackrel{(\text{law})}{=} \left(2 \sup_{0 \leq s \leq t} \int_0^s \text{sgn}(-Y_u) dY_u, t \geq 0 \right) \quad (7)$$

One can actually see Tanaka's formula as an example of extension of Itô's formula (see **Itô's Formula**).

Local time is also involved in inequalities reminiscent of the Burkholder–Davis–Gundy ones. Indeed, in [2], it is shown that there exist two universal positive and finite constants c and C such that

$$cE[\sup_t |X_t|] \leq E[\sup_a L_\infty^a] \leq CE[\sup_t |X_t|] \quad (8)$$

for any continuous local martingale X with $X_0 = 0$.

Local Time of a Markov Process

One can define the local time process of a Markov process X at a value b of its state space only if b is *regular* for X (see **Markov Processes** for the definition of Markov process). This means that starting from b , the process X then visits b at arbitrarily small times. Not every Markov process has this property. For example, a real-valued Lévy process (see **Lévy Processes** for the definition of that process) has this property at every point if its characteristic exponent ψ satisfies [3, Chapter II]

$$\int_{-\infty}^{+\infty} \mathcal{R}\left(\frac{1}{1 + \psi(x)}\right) dx < \infty \quad (9)$$

When b is regular for X , there exists a unique (up to a multiplicative constant) increasing continuous *additive functional*, that is, an adapted process $(\ell_t^b(X), t \geq 0)$ starting from 0 such that

$$\ell_{t+s}^b(X) = \ell_t^b(X) + \ell_s^b(X) \circ \theta_t \quad (10)$$

increasing only at times when X takes the value b . This process is called the *local time* at b .

When it exists, the local time process $(\ell_t^b(X), b \in E, t \geq 0)$ of a Markov process X with state space E might be jointly continuous in b and t . A necessary and sufficient condition for that property is given in [1] for Lévy processes as follows: set $h(a) = \frac{1}{\pi} \int_{-\infty}^{\infty} (1 - \cos ab) \mathcal{R}(1/\psi(b)) db$ and $m(\varepsilon) = \int_{\mathbb{R}} da 1_{\{h(a) < \varepsilon\}}$ for $\varepsilon > 0$; then the considered Lévy process has a continuous local time process if

$$\int_{0+} \sqrt{\text{Log}\left(\frac{1}{m(\varepsilon)}\right)} d\varepsilon < \infty \quad (11)$$

This result concerning Lévy processes has been extended to symmetric Markov processes in [7] and to general Markov processes in [4].

We mention that under condition (9), the local time process of a Lévy process X satisfies the same

occupation time formula as for the real Brownian motion:

$$\int_0^t f(X_s) ds = \int_E f(b) \ell_t^b(X) db \quad (12)$$

In case a random process is both a Markov process with regular points and a semimartingale, it then admits two local time processes that are different (they might coincide as in the case of the Brownian motion). As an example, consider a symmetric stable process X with index in $(1, 2)$ (for definition see **Lévy Processes**). We have $[X]^c = 0$; hence, as a semimartingale, X has a local time process that identically equals 0. However, as a Markov process, X has a local time process that satisfies formula (12) and hence differs from 0. Besides, in this case, condition (11) is satisfied.

NATHALIE EISENBAUM

Stochastic Integrals

If H_t represents the number of shares of a certain asset held by an investor and X_t denotes the price of the asset, the gain on $[0, t]$ from the trading strategy H is often represented as

$$\int_0^t H_t dX_t \quad (1)$$

Here, our goal is to give a precise meaning to such “stochastic integrals”, where H and X are stochastic processes verifying appropriate assumptions.

Looking at the time-series data for price evolution of, say, a stock, one realizes that placing smoothness assumptions, such as differentiability, on the paths of X would be unrealistic. Consequently, this puts us in a situation where the theory of ordinary integration is no longer sufficient for our purposes. In what follows, we construct the stochastic integral $\int H dX$ for a class of integrands and integrators that are as large as possible while satisfying certain conditions. The stochastic processes that we use are defined on a complete probability space $(\Omega, \mathcal{F}, \mathbb{P})$. We always assume that all the processes are jointly measurable, that is, for any process $(Y_t)_{0 \leq t < \infty}$ the map $(t, \omega) \mapsto Y_t(\omega)$ is measurable with respect to $\mathcal{B}(\mathbb{R}_+) \times \mathcal{F}$, where $\mathcal{B}(\mathbb{R}_+)$ is the Borel σ -algebra on $[0, \infty)$. In addition, we are given a *filtration* $(\mathcal{F}_t)_{0 \leq t \leq \infty}$ (see **Filtrations**), which models the accumulation of our information over time. The filtration $(\mathcal{F}_t)_{0 \leq t \leq \infty}$ is usually denoted by $\mathbb{F}$ for convenience. We say that a jointly measurable process, Y , is *adapted* (or *$\mathbb{F}$ -adapted* if we need to specify the filtration) if $Y_t \in \mathcal{F}_t$ for all $t, 0 \leq t < \infty$. We assume that the following hypotheses hold true.

Assumption 1 *The filtered complete probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ satisfies the usual hypotheses (see **Filtrations**)*

Although the above hypotheses are restrictive, they are satisfied in many situations. The natural filtration of a Lévy process, in particular a Brownian motion, satisfies the usual hypotheses once completed. The same is true for the natural filtration of any counting process or “reasonable” strong Markov process (see, e.g., [7] for a more detailed discussion of the usual hypotheses and their consequences).

Having fixed the stochastic base on which all the processes are defined, let us go back to our primary task of defining the integral $\int H dX$. If X is a process of finite variation, the theory is that of *Lebesgue–Stieltjes integration*.

Definition 1 *A stochastic process X is said to be càdlàg (for continu à droite, limites à gauche from French) if it a.s. has sample paths that are right continuous on $[0, \infty)$ with left limits on $(0, \infty)$. Similarly, a stochastic process X is said to be càglàd (for continu à gauche, limites à droite) if it a.s. has sample paths that are left continuous on $(0, \infty)$ with right limits on $[0, \infty)$. We denote the space of adapted, càdlàg (respectively, càglàd) processes by $\mathbb{D}$ (respectively, $\mathbb{L}$).*

Definition 2 *Let X be a càdlàg process. For a given $\omega \in \Omega$, the variation of the path $X(\omega)$ on the compact interval $[a, b]$ is defined as*

$$\sup_{\pi \in P} \sum_{t_i \in \pi} |X_{t_{i+1}}(\omega) - X_{t_i}(\omega)| \quad (2)$$

where P is the set of all finite partitions of $[a, b]$. X is said to be a *finite variation (FV) process* if X is càdlàg and almost all paths of X have finite variation on each compact interval of $[0, \infty)$.

If X is an FV process, for fixed ω , it induces a signed measure on $\mathbb{R}_+$ and thus we can define a jointly measurable integral $\int_0^t H_s(\omega) dX_s(\omega)$ for any bounded and jointly measurable H . In other words, the integral $\int H dX$ can be defined path by path as a Lebesgue–Stieltjes integral, if H is a jointly measurable process such that $\int_0^t H_s(\omega) dX_s(\omega)$ exists and is finite for all $t > 0$, a.s.

Unfortunately, the set of FV processes is not rich enough if one wants to give a rigorous meaning to $\int H dX$ using only Stieltjes integration. When we replace X with, say, a Brownian motion, the theory of Stieltjes integration fails to work since the Brownian motion is known to have paths of infinite variation in every compact interval of $\mathbb{R}_+$. Therefore, one needs to develop a concept of integration with respect to a class of processes that is large enough to cover processes such as the Brownian motion or the more general Lévy processes, which find frequent applications in different fields.

To find the weakest conditions on X so that $\int H dX$ is well defined, we start with the simplest

possible form for the integrand H and work gradually to extend the stochastic integral to more complex integrands by imposing conditions on X but making sure that these conditions are as minimal as possible at the same time.

The simplest integrand one can think of is of the following form:

$$\begin{aligned} H_t(\omega) &= \mathbf{1}_{[S(\omega), T(\omega)]}(t) \\ &:= \begin{cases} 1 & \text{if } S(\omega) < t \leq T(\omega) \\ 0 & \text{otherwise} \end{cases} \end{aligned} \quad (3)$$

where S and T are stopping times (see **Filtrations**) with respect to $\mathbb{F}$. In financial terms, this corresponds to a buy-and-hold strategy, whereby one unit of the asset is bought at, possibly random, time S and sold at time T . If X is the stochastic process representing the price of the asset, the net profit of such a trading strategy after time T is equal to $X_T - X_S$. This leads us to define $\int H dX$ as

$$\int_0^t H_s dX_s = X_{t \wedge T} - X_{t \wedge S} \quad (4)$$

where $t \wedge T := \min\{t, T\}$ for all t , $0 \leq t < \infty$, and stopping times T . Clearly, the process H in equation (3) has paths that are left continuous and possess right limits. We could similarly have defined $\int H dX$ for H of the form, say, $\mathbf{1}_{[S, T)}$. However, there is a good reason for insisting on paths that are continuous from the left on $(0, \infty)$ as we see in Example 1. Let us denote $\int_0^t H_s dX_s$ by $(H \cdot X)_t$.

Theorem 1 *Let H be of the form (3) and M be a martingale (see **Martingales**). Then $H \cdot M$ is a martingale.*

Later, we will see that the above theorem holds for a more general class of integrands so that the stochastic integrals preserve the martingale property. The following example shows why the left continuity for H is a reasonable restriction from a financial perspective.

Example 1 Let N be a Poisson process with intensity λ and define X by $X_t = \lambda t - N_t$. It is well known that X is a martingale. Suppose that there exists a traded asset with a price process given by X . Under normal circumstances, one should not be able to make arbitrage profits by trading in this

asset since its price does not change over time on average. Indeed, if H is of the form (3), then $H \cdot X$ is a martingale with expected value zero so that the traders earn zero profit on average, as expected. Now consider another strategy $H = \mathbf{1}_{[0, T_1]}$, where T_1 is the time of the first jump of N . Since X is an FV process, $H \cdot X$ is well defined as a Stieltjes integral and is given by $(H \cdot X)_t = \lambda(t \wedge T_1) > 0$, a.s., being the value of the portfolio at time t . Thus, this trading strategy immediately accumulates arbitrage profits. A moment of reflection reveals that such a trading strategy is not feasible under usual circumstances since it requires the knowledge of the time of a market crash, time T_1 in this case, before it happens. If we use $H = \mathbf{1}_{[0, T_1]}$ instead, this problem disappears.

Naturally, one will want the stochastic integral to be linear. Given a linear integral operator, we can define $H \cdot X$ for integrands that are linear combinations of processes of the form (3).

Definition 3 *A process H is said to be simple predictable if H has a representation*

$$H_t = H_0 \mathbf{1}_{\{0\}}(t) + \sum_{i=1}^n H_i \mathbf{1}_{(T_i, T_{i+1}]}(t) \quad (5)$$

where $0 = T_1 \leq \dots \leq T_{n+1} < \infty$ is a finite sequence of stopping times, $H_0 \in \mathcal{F}_0$, $H_i \in \mathcal{F}_{T_i}$, $1 \leq i \leq n$ with $|H_i| < \infty$, a.s., $0 \leq i \leq n$. The collection of simple predictable processes is denoted by $\mathbf{S}$.

Let $\mathbf{L}^0$ be the space of finite-valued random variables endowed with the topology of convergence in probability. Define the linear mapping $I_X : \mathbf{S} \mapsto \mathbf{L}^0$ as

$$\begin{aligned} I_X(H) &= (H \cdot X)_\infty \\ &:= H_0 X_0 + \sum_{i=1}^n H_i (X_{T_{i+1}} - X_{T_i}) \end{aligned} \quad (6)$$

where H has the representation given in equation (5). Note that this definition does not depend on the particular choice of representation for H .

Another property that the operator I_X must have is that it should satisfy some version of the bounded convergence theorem. This will inevitably place some restrictions on the stochastic process X . Thus, to have a large enough class of integrators, we choose a

reasonably weak version. A particularly weak version of the bounded convergence theorem is that the *uniform* convergence of H^n to H in $\mathbf{S}$ implies the convergence of $I_X(H^n)$ to $I_X(H)$ only in *probability*. Let $\mathbf{S}_u$ be the space $\mathbf{S}$ topologized by uniform convergence and recall that for a process X and a stopping time T , the notation X^T denotes the process $(X_{t \wedge T})_{t \geq 0}$.

Definition 4 A process X is a *total semimartingale* if X is càdlàg, adapted and $I_X : \mathbf{S}_u \mapsto \mathbf{L}^0$ is continuous. X is a *semimartingale* (see **Semimartingale**) if, for each $t \in [0, \infty)$, X^t is a total semimartingale.

This continuity property of I_X allows us to extend the definition of stochastic integrals to a class of integrands that is larger than $\mathbf{S}$ when the integrator is a semimartingale.

It follows from the definition of a semimartingale that semimartingales form a vector space. One can also show that all square integrable martingales and all adapted FV processes are semimartingales (see **Semimartingale**). Therefore, the sum of a square integrable martingale and an adapted FV process would also be a semimartingale. The converse of this statement is also “essentially” true. The precise statement is the following theorem.

Theorem 2 (Bichteler–Dellacherie Theorem). Let X be a semimartingale. Then there exist processes M, A , with $M_0 = A_0 = 0$ such that

$$X_t = X_0 + M_t + A_t \quad (7)$$

where M is a local martingale and A is an adapted FV process.

Here, we emphasize that this decomposition is not necessarily unique. Indeed, suppose that X has the decomposition $X = X_0 + M + A$ and the space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ supports a Poisson process N with intensity λ . Then $Y_t = N_t - \lambda t$ will define a martingale, which is also an FV process. Therefore, X can also be written as $X = X_0 + (M + Y) + (A - Y)$. The reason for the nonuniqueness is the existence of martingales that are of finite variation. However, if X has a decomposition $X = X_0 + M + A$, where M is a local martingale and A is *predictable*^a and FV with $M_0 = A_0 = 0$, then such a decomposition is unique since all predictable local martingales that are of finite variation have to be constant.

Arguably, Brownian motion is the most well known of all semimartingales. In the following section, we develop stochastic integration with respect to a Brownian motion.

L^2 Theory of Stochastic Integration with Respect to Brownian Motion

We assume that there exists a Brownian motion, B , on $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ with $B_0 = 0$, and that $\mathcal{F}_0$ only contains the $(\mathcal{F}, \mathbb{P})$ -null sets. First, we define the notion of *predictability*, which is the key concept in defining the stochastic integral.

Definition 5 The *predictable σ -algebra* $\mathcal{P}$ on $[0, \infty) \times \Omega$ is defined to be the smallest σ -algebra on $[0, \infty) \times \Omega$ with respect to which every adapted càglàd process is measurable. A process is said to be *predictable* if it is a $\mathcal{P}$ -measurable map from $[0, \infty) \times \Omega$ to $\mathbb{R}$.

Clearly, $\mathbf{S} \subset \mathcal{P}$. Actually, there is more to this as is shown by the next theorem.

Theorem 3 Let $\mathbf{bS}$ be the set of elements of $\mathbf{S}$ that are bounded a.s. Then, $\mathcal{P} = \sigma(\mathbf{bS})$, that is, $\mathcal{P}$ is generated by the processes in $\mathbf{bS}$.

By linearity of the stochastic integral and Theorem 1 and using the fact that Brownian motion has increments independent from the past with a certain Gaussian distribution, we have the following.

Theorem 4 Let $H \in \mathbf{bS}$ and define $(H \cdot B)_t = (H \cdot B^t)_\infty$, that is, $(H \cdot B)_t$ is the stochastic integral of H with respect to B^t . Then $H \cdot B$ is a martingale and

$$\mathbb{E}[(H \cdot B)_t^2] = \int_0^t \mathbb{E}[H_s^2] \, ds \quad (8)$$

In the following, we construct the stochastic integral with respect to Brownian motion for a subset of predictable processes. To keep the exposition simple, we restrict our attention to a finite interval $[0, T]$, where T is arbitrary but deterministic. Define

$$\mathcal{L}^2(B^T) := \left\{ H \in \mathcal{P} : \int_0^T \mathbb{E}[H_s^2] \, ds < \infty \right\} \quad (9)$$

which is a Hilbert space. Note that $\mathbf{bS} \subset \mathcal{L}^2(B^T)$. Letting $L^2(\mathcal{F}_T)$ denote the space of square integrable

$\mathcal{F}_T$ -measurable random variables, Theorem 4 now implies the map

$$I_{B^T} : \mathbf{bS} \mapsto \mathcal{L}^2(\mathcal{F}_T) \quad (10)$$

defined by

$$I_{B^T}(H) = (H \cdot B)_T \quad (11)$$

is an isometry. Consequently, we can extend the definition of the stochastic integral uniquely to the closure of $\mathbf{bS}$ in $\mathcal{L}^2(B^T)$. An application of monotone class theorem along with Theorem 3 yields that the closure is the whole $\mathcal{L}^2(B^T)$.

Theorem 5 *Let $H \in \mathcal{L}^2(B^T)$. Then the Itô integral $(H \cdot B)_T$ of H with respect to B^T is the image of H under the extension of the isometry I_{B^T} to the whole of $\mathcal{L}^2(B^T)$. In particular,*

$$\mathbb{E}[(H \cdot B)_T^2] = \int_0^T \mathbb{E}[H_s^2] \, ds \quad (12)$$

Moreover, the process Y defined by $Y_t = (H \cdot B)_{t \wedge T}$ is a square integrable martingale.

The property (12) is often called the *Itô isometry*.

Stochastic Integration with Respect to General Semimartingales

In the previous section, we developed the stochastic integration for Brownian motion over the interval $[0, T]$. We need to mention here that the method employed works not only for Brownian motion but also for any martingale M that is square integrable over $[0, T]$, the latter case requiring some extra effort mainly for establishing the existence of the so-called *quadratic variation* process associated with M . This would, in turn, allow us to extend the definition of the stochastic integral with respect to X of the form $X = M + A$, where M is a square integrable martingale and A is a process of finite variation on compacts by defining, under some conditions on H ,

$$H \cdot X = H \cdot M + H \cdot A \quad (13)$$

where $H \cdot A$ can be computed as a path-by-path Lebesgue–Stieltjes integral. In this section, we establish the stochastic integral with respect to a general semimartingale. The idea would be similar to the construction of the stochastic integral with respect to

Brownian motion. We show that the integral operator is a continuous mapping from the set of simple predictable process into an appropriate space so that we can extend the set of possible integrands to the closure of $\mathbf{S}$ in a certain topology.

Definition 6 *A sequence of processes $(H^n)_{n \geq 1}$ converges to a process H uniformly on compacts in probability (UCP) if, for each $t > 0$, $\sup_{0 \leq s \leq t} |H_s^n - H_s|$ converges to 0 in probability.*

The following result is not surprising and one can refer to, for example, [7] for a proof.

Theorem 6 *The space $\mathbf{S}$ is dense in $\mathbb{L}$ under the UCP topology.*

The following mapping is key to defining the stochastic integral with respect to a general semimartingale.

Definition 7 *For $H \in \mathbf{S}$ and X being a càdlàg process, define the linear mapping $J_X : \mathbf{S} \mapsto \mathbb{D}$ by*

$$J_X(H) = H_0 X_0 + \int_{i=1}^n H_i (X^{T_{i+1}} - X^{T_i}) \quad (14)$$

where H has the representation as in equation (5).

Note the difference between J_X and I_X . I_X maps processes into random variables, whereas J_X maps processes into processes.

Definition 8 *For $H \in \mathbf{S}$ and X being an adapted càdlàg process, we call $J_X(H)$ the stochastic integral of H with respect to X .*

Observe that $J_X(H)_t = I_{X^t}(H)$. This property, combined with the definition of a semimartingale, yields the following continuity property for J_X .

Theorem 7 *Let X be a semimartingale and $\mathbf{S}_{\text{UCP}}$ (respectively $\mathbb{D}_{\text{UCP}}$) denote the space $\mathbf{S}$ (respectively, $\mathbb{D}$) endowed with the UCP topology. Then the mapping $J_X : \mathbf{S}_{\text{UCP}} \mapsto \mathbb{D}_{\text{UCP}}$ is continuous.*

Using Theorem 6, we can now extend the integration operator J_X from $\mathbf{S}$ to $\mathbb{L}$ by continuity, since $\mathbb{D}_{\text{UCP}}$ is a complete metric space^b.

Definition 9 *Let X be a semimartingale. The continuous linear mapping $J_X : \mathbb{L}_{\text{UCP}} \mapsto \mathbb{D}_{\text{UCP}}$ obtained as the extension of $J_X : \mathbf{S}_{\text{UCP}} \mapsto \mathbb{D}_{\text{UCP}}$ is called the stochastic integral.*

Note that, in contrast to the L^2 theory utilized in the previous section, we do not need to impose any integrability conditions on either X or H to establish the existence of the stochastic integral $H \cdot X$ as long as H remains in $\mathbb{L}$. The above continuity property of the stochastic integrals moreover allows us to approximate the $H \cdot X$ using the Riemann sums.

Definition 10 Let σ denote a finite sequence of finite stopping times:

$$0 = T_0 \leq T_1 \leq \dots \leq T_k < \infty. \quad (15)$$

The sequence of σ is called a random partition. A sequence of random partitions σ_n

$$\sigma_n : 0 = T_0^n \leq T_1^n \leq \dots \leq T_{k_n}^n \quad (16)$$

is said to tend to identity if

1. $\lim_{n \rightarrow \infty} \sup_j T_j^n = \infty$, a.s. and
2. $\sup_j |T_{j+1}^n - T_j^n|$ converges to 0 a.s.

Let Y be a process and σ be a random partition. Define the process

$$Y^\sigma := Y_0 \mathbf{1}_{\{0\}} + \sum_j Y_{T_j} \mathbf{1}_{(T_j, T_{j+1}]} \quad (17)$$

Consequently, if Y is in $\mathbb{D}$ or $\mathbb{L}$

$$Y^\sigma \cdot X = Y_0 X_0 + \sum_j Y_{T_j} (X^{T_{j+1}} - X^{T_j}) \quad (18)$$

for any semimartingale X .

Theorem 8 Let X be a semimartingale and let $\int_{0+}^t H_s dX_s$ denote $(H \cdot X)_t - H_0 X_0$ for any $H \in \mathbb{L}$. If Y is a process in $\mathbb{D}$ or in $\mathbb{L}$, and (σ_n) is a sequence of random partitions tending to identity, then the process $\left(\int_{0+}^t Y_s^{\sigma_n} dX_s \right)_{t \geq 0}$ converges to the stochastic integral $(Y_-) \cdot X$ in UCP, where Y_- is the process defined as $(Y_-)_s = \lim_{r \rightarrow s, r < s} Y_r$, for $s > 0$, and $(Y_-)_0 = 0$.

Example 2 As an application of the above theorem, we calculate $\int_0^t B_s dB_s$, where B is a standard Brownian motion with $B_0 = 0$. Let (σ_n) be a sequence of random partitions of the form (16) tending to identity and let $B^n = B^{\sigma_n}$. Note that

$$\begin{aligned} \int_0^t B_s^n dB_s &= \sum_{\substack{t_j \in \sigma_n \\ t_j < t}} B_{t_j} (B_{t \wedge t_{j+1}} - B_{t_j}) \\ &= \sum_{\substack{t_j \in \sigma_n \\ t_j < t}} \frac{1}{2} (B_{t \wedge t_{j+1}} + B_{t_j}) (B_{t \wedge t_{j+1}} - B_{t_j}) \\ &\quad - \sum_{\substack{t_j \in \sigma_n \\ t_j < t}} \frac{1}{2} (B_{t \wedge t_{j+1}} - B_{t_j})^2 \\ &= \frac{1}{2} B_{(t \wedge T_{k_n}^n)}^2 - \frac{1}{2} \sum_{\substack{t_j \in \sigma_n \\ t_j < t}} (B_{t_{j+1}} - B_{t_j})^2 \end{aligned} \quad (19)$$

As n tends to ∞ , the sum^c in equation (19) is known to converge to t . Obviously, $B_{T_{k_n}^n \wedge t}^2$ tends to B_t^2 since σ_n tends to identity. Thus, we conclude via Theorem 8 that

$$\int_0^t B_s dB_s = \frac{1}{2} B_t^2 - \frac{t}{2} \quad (20)$$

since B is continuous with $B_0 = 0$. Thus, the integration rules for a stochastic integral are quite different from those for an ordinary integral. Indeed, if A were a continuous process of finite variation with $A_0 = 0$, then the Riemann–Stieltjes integral of $A \cdot A$ will yield the following formula:

$$\int_0^t A_s dA_s = \frac{1}{2} A_t^2 \quad (21)$$

As in the case of Brownian motion, stochastic integration with respect to a semimartingale preserves the martingale property.

Theorem 9 Let $H \in \mathbb{L}$ such that $\lim_{t \downarrow 0} |H_t| < \infty$ and X be a local martingale (see **Martingales**). Then $H \cdot X$ is also a local martingale.

Next, we would like to weaken the restriction that an integrand must be in $\mathbb{L}$. If we want the stochastic integral to still preserve the martingale property with this extended class of integrands, we inevitably need to restrict our attention to predictable processes. To see this, consider the process $H = \mathbf{1}_{[0, T_1)}$ in Example 1. This process is not predictable since the jump times of a Poisson process are not predictable stopping times. As we have shown in Example 1, the

integral of H with respect to a particular martingale is not a martingale.

Before we allow more general predictable integrands in a stochastic integral, we need to develop the notion of *quadratic variation* of a semimartingale. This is discussed in the following section.

Properties of Stochastic Integrals

In this section, H denotes an element of $\mathbb{L}$ and X denotes a semimartingale. For a process $Y \in \mathbb{D}$, we define $\Delta Y_t = Y_t - Y_{t-}$, the jump at t . Recall that two processes Y and Z are said to be *indistinguishable* if $\mathbb{P}\{\omega : Y_t(\omega) = Z_t(\omega), \forall t\} = 1$.

Theorem 10 *Let T be a stopping time. Then $(H \cdot X)^T = H \mathbf{1}_{[0, T]} \cdot X = H \cdot (X^T)$.*

Theorem 11 *The jump process $(\Delta(H \cdot X))_{t \geq 0}$ is indistinguishable from $(H_t \Delta X_t)_{t \geq 0}$.*

In finance theory, one often needs to work under the so-called *risk-neutral* measure rather than the empirical or objective measure $\mathbb{P}$. Recall that definitions of a semimartingale and its stochastic integral are given in spaces topologized by convergence in probability. Thus, one may wonder whether the value of a stochastic integral remains unchanged under an equivalent change of measure. The following theorem shows that this is indeed the case. Let $\mathbb{Q}$ be another probability measure on $(\Omega, \mathcal{F})$ and let $H_{\mathbb{Q}} \cdot X$ denote the stochastic integral of H with respect to X computed under $\mathbb{Q}$.

Theorem 12 *Let $\mathbb{Q} \ll \mathbb{P}$. Then, $H_{\mathbb{Q}} \cdot X$ is indistinguishable from $H_{\mathbb{P}} \cdot X$.*

Theorem 13 *Let $\mathbb{G} = (\mathcal{G}_t)_{t \geq 0}$ be another filtration such that H is in both $\mathbb{L}(\mathbb{G})$ and $\mathbb{L}(\mathbb{F})$, and such that X is also a $\mathbb{G}$ -semimartingale. Then $H_{\mathbb{G}} \cdot X$ is indistinguishable from $H_{\mathbb{F}} \cdot X$.*

The following theorem shows the stochastic integral is an extension of the Lebesgue–Stieltjes integral.

Theorem 14 *If X is an FV process, then $H \cdot X$ is indistinguishable from the Lebesgue–Stieltjes integral, computed path by path. Consequently, $H \cdot X$ is an FV process.*

Theorem 15 *The stochastic integral is associative. That is, $H \cdot X$ is also a semimartingale and if $G \in \mathbb{L}$*

$$G \cdot (H \cdot X) = (GH) \cdot X \quad (22)$$

Definition 11 *The quadratic variation process of X , denoted by $[X, X] = ([X, X]_t)_{t \geq 0}$, is defined as*

$$[X, X] = X^2 - 2X_- \cdot X \quad (23)$$

Recall that $X_{0-} = 0$. Let Y be another semimartingale. The quadratic covariation of X and Y , denoted by $[X, Y]$, is defined as

$$[X, Y] = XY - Y_- \cdot X - X_- \cdot Y \quad (24)$$

Since X_- (and Y_-) belongs to $\mathbb{L}$, we can use Theorem 8 to deduce the following.

Theorem 16 *Let Y be a semimartingale. The quadratic covariation $[X, Y]$ of X and Y is an adapted càdlàg process that satisfies the following:*

1. $[X, Y]_0 = X_0 Y_0$ and $\Delta[X, Y] = \Delta X \Delta Y$.
2. If (σ_n) is a sequence of partitions tending to identity, then

$$\begin{aligned} X_0 Y_0 + \sum_j (X^{T_{j+1}^n} - X^{T_j^n}) \\ \times (Y^{T_{j+1}^n} - Y^{T_j^n}) \rightarrow [X, Y] \end{aligned} \quad (25)$$

with convergence in UCP, where σ_n is of the form (16).

3. If T is any stopping time, then $[X^T, Y] = [X, Y^T] = [X, Y]^T$. Moreover, $[X, X]$ is increasing.

Since $[X, X]$ is increasing and càdlàg by definition, we immediately deduce that $[X, X]$ is of finite variation. Moreover, the following polarization identity

$$[X, Y] = \frac{1}{2}([X + Y, X + Y] - [X, X] - [Y, Y]) \quad (26)$$

reveals that $[X, Y]$ is the difference of two increasing processes; therefore, $[X, Y]$ is an FV process as well. This, in turn, implies XY is also a semimartingale and yields the *integration by parts* formula:

$$X_t Y_t = (X_- \cdot Y)_t + (Y_- \cdot X)_t + [X, Y]_t \quad (27)$$

When X and Y are FV processes, the classical integration by parts formula reads as follows:

$$X_t Y_t = X_0 Y_0 + (X_- \cdot Y)_t + (Y_- \cdot X)_t + \sum_{0 < s \leq t} \Delta X_s \Delta Y_s \quad (28)$$

Therefore, if X or Y is a continuous processes of finite variation, then $[X, Y] = X_0 Y_0$. In particular, if X is a continuous FV process, then its quadratic variation is equal to X_0^2 .

Theorem 17 *Let X and Y be two semimartingales, and let H and K be two measurable processes. Then one has a.s.*

$$\begin{aligned} & \int_0^\infty |H_s| |K_s| \, d[X, Y]_s \\ & \leq \left(\int_0^\infty H_s^2 \, d[X, X]_s \right)^{\frac{1}{2}} \left(\int_0^\infty K_s^2 \, d[Y, Y]_s \right)^{\frac{1}{2}} \end{aligned} \quad (29)$$

The above inequality is called *Kunita–Watanabe inequality*. An immediate consequence of this inequality is that if X or Y has zero quadratic variation, then $[X, Y] = 0$. The following theorem follows from the definition of quadratic variation and Theorem 9.

Theorem 18 *Let X be a local martingale. Then, $X^2 - [X, X]$ is a local martingale. Moreover, $[X, X]$ is the unique adapted càdlàg and FV process A such that $X^2 - A$ is a local martingale and $\Delta A = (\Delta X)^2$ with $A_0 = X_0^2$.*

Note that the uniqueness in the above theorem is lost if we do not impose $\Delta A = (\Delta X)^2$. Roughly speaking, the above theorem infers $\mathbb{E}(X_t^2) = \mathbb{E}([X, X]_t)$ when X is a martingale. The following theorem formalizes this intuition.

Corollary 1 *Let X be a local martingale. Then, X is a martingale with $\mathbb{E}(X_t^2) < \infty$, for all $t \geq 0$, if and only if $\mathbb{E}([X, X]_t) < \infty$, for all $t \geq 0$. If $\mathbb{E}([X, X]_t) < \infty$, then $\mathbb{E}(X_t^2) = \mathbb{E}([X, X]_t)$.*

The following corollary to Theorem 18 is of fundamental importance in the theory of martingales.

Corollary 2 *Let X be a continuous local martingale, and $S \leq T \leq \infty$ be stopping times. If X has paths of finite variation on the stochastic interval (S, T) ,*

then X is constant on $[S, T]$. Moreover, if $[X, X]$ is constant on $[S, T] \cap [0, \infty)$, then X is also constant there.

The following result is quite handy when it comes to the calculation of the quadratic covariation of two stochastic integrals.

Theorem 19 *Let Y be a semimartingale and $K \in \mathbb{L}$. Then*

$$[H \cdot X, K \cdot Y]_t = \int_0^t H_s K_s \, d[X, Y]_s \quad (30)$$

In the following section, we define the stochastic integral for predictable integrals. However, we already have all the results to present the celebrated *Itô's formula*.

Theorem 20 (Itô's Formula). *Let X be a semimartingale and f be a C^2 real function. Then $f(X)$ is again a semimartingale and the following formula holds:*

$$\begin{aligned} f(X_t) - f(X_0) &= \int_{0+}^t f'(X_{s-}) \, dX_s \\ &+ \frac{1}{2} \int_{0+}^t f''(X_{s-}) \, d[X, X]_s \\ &+ \sum_{0 < s \leq t} \left\{ f(X_s) - f(X_{s-}) - f'(X_{s-}) \Delta X_s \right. \\ &\quad \left. - \frac{1}{2} f''(X_{s-}) (\Delta X_s)^2 \right\} \end{aligned} \quad (31)$$

Stochastic Integration for Predictable Integrands

In this section, we weaken the hypothesis that $H \in \mathbb{L}$ in order for $H \cdot X$ to be well defined for a semimartingale X . As explained earlier, we restrict our attention to predictable processes since we want the stochastic integral to preserve the martingale property. We will not be able to show the existence of stochastic integral $H \cdot X$ for all $H \in \mathcal{P}$ but, as in the section L^2 Theory of Stochastic Integration with Respect to Brownian Motion, we give a meaning to $H \cdot X$ for the appropriately integrable processes in $\mathcal{P}$. First, we assume that X is a special semimartingale, that is, there exist processes M and A such that M is a

local martingale and A is predictable and of finite variation with $M_0 = A_0 = 0$ and $X = X_0 + M + A$. This decomposition of a special semimartingale is unique and called the *canonical decomposition*. Without loss of generality, let us assume that $X_0 = 0$.

Definition 12 Let X be a special semimartingale with the canonical decomposition $X = M + A$. The $\mathcal{H}^2$ norm of X is defined as

$$\|X\|_{\mathcal{H}^2} := \| [M, M]_{\infty}^{1/2} \|_{L^2} + \left\| \int_0^{\infty} |dA_s| \right\|_{L^2} \quad (32)$$

The space of $\mathcal{H}^2$ semimartingales consists of special semimartingales with finite $\mathcal{H}^2$ norm. We write $X \in \mathcal{H}^2$ to indicate that X belongs to the space of $\mathcal{H}^2$ semimartingales.

One can show that the space of $\mathcal{H}^2$ semimartingales is a Banach space, which is the key property to extend the definition of stochastic integrals for a more general class of integrands. Let $\mathbf{b}\mathbb{L}$ denote the space of bounded adapted processes with càglàd paths and $\mathbf{b}\mathcal{P}$ denote the space of bounded predictable processes.

Definition 13 Let $X \in \mathcal{H}^2$ with the canonical decomposition $X = N + A$ and let $H, J \in \mathbf{b}\mathcal{P}$. We define the metric $d_X(H, J)$ as

$$d_X(H, J) := \left\| \left(\int_0^{\infty} (H_s - J_s)^2 d[M, M]_s \right)^{1/2} \right\|_{L^2} + \left\| \int_0^{\infty} |H_s - J_s| dA_s \right\|_{L^2} \quad (33)$$

From the monotone class theorem, we obtain the following.

Theorem 21 For $X \in \mathcal{H}^2$, the space $\mathbf{b}\mathbb{L}$ is dense in $\mathbf{b}\mathcal{P}$ under $d_X(\cdot, \cdot)$.

It is straightforward to show that if $H \in \mathbf{b}\mathbb{L}$ and $X \in \mathcal{H}^2$, then $H \cdot X \in \mathcal{H}^2$. The following is an immediate consequence of the definition of $d_X(\cdot, \cdot)$.

Theorem 22 Let $X \in \mathcal{H}^2$ and $(H^n) \subset \mathbf{b}\mathbb{L}$ such that (H^n) is Cauchy under $d_X(\cdot, \cdot)$. Then, $(H^n \cdot X)$ is Cauchy in $\mathcal{H}^2$.

Moreover, it is easy to show that if $(H^n) \subset \mathbf{b}\mathbb{L}$ and $(J^n) \subset \mathbf{b}\mathbb{L}$ converge to the same limit under $d_X(\cdot, \cdot)$, then $(H^n \cdot X)$ and $(J^n \cdot X)$ converge to the same limit in $\mathcal{H}^2$. Thus, we can now define the stochastic integral $H \cdot X$ for any $H \in \mathbf{b}\mathcal{P}$.

Definition 14 Let $X \in \mathcal{H}^2$ and $H \in \mathbf{b}\mathcal{P}$. Let $(H^n) \subset \mathbf{b}\mathbb{L}$ such that $\lim_{n \rightarrow \infty} d_X(H^n, H) = 0$. The stochastic integral $H \cdot X$ is the unique semimartingale $Y \in \mathcal{H}^2$ such that $\lim_{n \rightarrow \infty} H^n \cdot X = Y$ in $\mathcal{H}^2$.

Note that if B is a standard Brownian motion, B is not in $\mathcal{H}^2$ but $B^T \in \mathcal{H}^2$ for any deterministic and finite T . Therefore, for any $H \in \mathbf{b}\mathcal{P}$, $H \cdot B^T$ is well defined. Moreover, $H \in \mathbf{b}\mathcal{P}$ implies $H \in \mathcal{L}^2(B^T)$ where $\mathcal{L}^2(B^T)$ is the space defined in the section L^2 Theory of Stochastic Integration with Respect to Brownian Motion. One can easily check that the stochastic integral $H \cdot B^T$ defined by Definition 14 is indistinguishable from the stochastic integral $H \cdot B^T$ defined in the section L^2 Theory of Stochastic Integration with Respect to Brownian Motion. Clearly, $\mathbf{b}\mathcal{P}$ is strictly contained in $\mathcal{L}^2(B^T)$, and we know from the section L^2 Theory of Stochastic Integration with Respect to Brownian Motion that it is possible to define the stochastic integral with respect to B^T for any process in $\mathcal{L}^2(B^T)$. Thus, it is natural to ask whether we can extend the stochastic integral given by Definition 14 to integrands that satisfy a certain square integrability condition.

Definition 15 Let $X \in \mathcal{H}^2$ with the canonical decomposition $X = M + A$. We say that $H \in \mathcal{P}$ is $(\mathcal{H}^2, X)$ integrable if

$$\mathbb{E} \left(\int_0^{\infty} H_s^2 d[M, M]_s \right) + \mathbb{E} \left(\left\{ \int_0^{\infty} |H_s| dA_s \right\}^2 \right) < \infty \quad (34)$$

It can be shown that if $H \in \mathcal{P}$ is $(\mathcal{H}^2, X)$ integrable, $(H^n \cdot X)$ is a Cauchy sequence in $\mathcal{H}^2$ where $H^n = H \mathbf{1}_{\{|H| \leq n\}}$ is in $\mathbf{b}\mathcal{P}$, which means that we can define the stochastic integral for such H .

Definition 16 Let $X \in \mathcal{H}^2$ and let $H \in \mathcal{P}$ be $(\mathcal{H}^2, X)$ integrable. The stochastic integral $H \cdot X$ is defined to be the $\lim_{n \rightarrow \infty} H^n \cdot X$, with convergence in $\mathcal{H}^2$, where $H^n = H \mathbf{1}_{\{|H| \leq n\}}$.

In the case $X = B^T$, $M = B^T$, and $A = 0$; therefore, H being $(\mathcal{H}^2, X)$ integrable is equivalent to the condition

$$\int_0^T \mathbb{E}(H_s^2) ds < \infty \quad (35)$$

which gives exactly the elements of $\mathcal{L}^2(B^T)$.

So far, we have been able to define the stochastic integral with predictable integrands only for semimartingales in $\mathcal{H}^2$. This seems to be a major restriction. However, as the following theorem shows, it is not. Recall that for a stopping time T , $X^{T-} = X\mathbf{1}_{[0, T)} + X_T - \mathbf{1}_{[T, \infty]}$.

Theorem 23 *Let X be a semimartingale, $X_0 = 0$. Then X is prelocally in $\mathcal{H}^2$. That is, there exists a nondecreasing sequence of stopping times (T^n) , $\lim_{n \rightarrow \infty} T^n = \infty$ a.s., such that $X^{T^n-} \in \mathcal{H}^2$, for each $n \geq 1$.*

Definition 17 *Let X be a semimartingale and $H \in \mathcal{P}$. The stochastic integral $H \cdot X$ is said to exist if there exists a sequence of stopping times (T^n) increasing to ∞ a.s. such that $X^{T^n-} \in \mathcal{H}^2$, for each $n \geq 1$, and such that H is $(\mathcal{H}^2, X^{T^n-})$ integrable for each $n \geq 1$. In this case, we write $H \in L(X)$ and define the stochastic integral as*

$$H \cdot X = H \cdot (X^{T^n-}), \quad \text{on } [0, T^n] \quad (36)$$

for each n .

A particular case when $H \cdot X$ is well defined is when H is locally bounded.

Theorem 24 *Let X be a semimartingale and $H \in \mathcal{P}$ be locally bounded. Then, $H \in L(X)$.*

We also have the martingale preservation property.

Theorem 25 *Let M be a local martingale and $H \in \mathcal{P}$ be locally bounded. Then, $H \cdot M$ is a local martingale.*

The general result that M a local martingale and $H \in L(M)$ implies that $H \cdot M$ is a local martingale is not true. The following example is due to Emery and can be taken as a starting point for a study of *sigma-martingales* (see **Equivalent Martingale Measures**).

Example 3 Let T be an exponential random variable with parameter 1 and let U be an independent

random variable with $\mathbb{P}(U = 1) = \mathbb{P}(U = -1) = 1/2$, and set $X = U\mathbf{1}_{[T, \infty)}$. Then, X is a martingale in its own filtration. Let H be defined as $H_t = \frac{1}{t}\mathbf{1}_{\{t > 0\}}$. H is a deterministic predictable integral. Note that H is not locally bounded, being only continuous on $(0, \infty)$. $H \cdot X$ exists as a Lebesgue–Stieltjes integral since X has paths of finite variation. However, $H \cdot X$ is not a local martingale since, for any stopping time S with $P(S > 0) > 0$, $\mathbb{E}(|(H \cdot X)_S|) = \infty$.

When M is a continuous local martingale, the theory becomes nicer.

Theorem 26 *Let M be a continuous local martingale and let $H \in \mathcal{P}$ be such that $\int_0^t H_s^2 d[M, M]_s < \infty$, for each $t \geq 0$. Then $H \in L(M)$ and $H \cdot M$ is a continuous local martingale.*

The question may arise as to whether the properties of stochastic integral stated for left-continuous integrands in the section Properties of Stochastic Integrals continue to hold when we allow predictable integrands. The answer is positive except for Theorems 13 and 14. Still, if X is a semimartingale with paths of finite variation on compacts and if $H \in L(X)$ is such that the Stieltjes integral $\int_0^t |H_s| |dX_s|$ exists a.s. for each $t \geq 0$, then the stochastic integral $H \cdot X$ agrees with the Stieltjes integral computed path by path. However, $H \cdot X$ is not necessarily an FV process. See [7, Exercise 45 in Chapter IV] of [7] for a counterexample. The analogous result for Theorem 13 is the following, which is particularly useful when one needs to study asymmetric information in financial markets where some traders possess extra information compared to others.

Theorem 27 *Let $\mathbb{G}$ be another filtration satisfying the usual hypotheses and suppose that $\mathcal{F}_t \subset \mathcal{G}_t$, each $t \geq 0$, and that X remains a semimartingale with respect to $\mathbb{G}$. Let H be locally bounded and predictable for $\mathbb{F}$. Then H is locally bounded and predictable for $\mathbb{G}$, the stochastic integral $H_{\mathbb{G}} \cdot X$ exists and is equal to $H_{\mathbb{F}} \cdot X$.*

It is important to have H locally bounded in the above theorem; see [4] for a counterexample in the context of enlargement of filtrations.

We end this section with the *dominated convergence theorem for stochastic integrals*.

Theorem 28 *Let X be a semimartingale and $(H^n) \subset \mathcal{P}$ be a sequence converging a.s. to a limit $H \in \mathcal{P}$. If there exists a process $G \in L(X)$ such that $|H^n| \leq G$, for all n , then $H^n \in L(X)$ for all n , $H \in L(X)$ and $(H^n \cdot X)$ converges to $H \cdot X$ in UCP.*

Concluding Remarks

In this article, we used the approach of Protter [7] to define the semimartingale as a good integrator and construct its stochastic integral. Another approach that is closely related is given by Chou *et al.* [1], who developed the stochastic integration for general predictable integrands with respect to a semimartingale in a space endowed with the semimartingale topology. Historically, the stochastic integral was first proposed for Brownian motion by Itô [3], then for continuous martingales, then for square integrable martingales, and finally for càdlàg processes that can be written as the sum of a locally square integrable local martingale and an FV process by J.L. Doob, H. Kunita, S. Watanabe, P. Courrège, P.A. Meyer, and others. Later in 1970, Doléans-Dade and Meyer [2] showed that the local square integrability condition could be relaxed, which led to the traditional definition of a semimartingale as a sum of a local martingale and an FV process. A different theory of stochastic integration, the *Itô-belated integral*, was developed by McShane [5]. It imposed different restrictions on the integrators and the integrands and used a theory of “gauges” and appeared to be very different from the approach here. It turns out, however, that when the integral $\int H dX$ made sense both as a stochastic integral in the sense developed here and as an Itô-belated integral, they were indistinguishable. See [6] for a comparison of these two integrals. Another related stochastic integral is called the *Fisk–Stratonovich (FS)* integral that was developed by Fisk and Stratonovich independently. The FS integral obeys the integration by parts formula for FV

processes when at least one of the integrand or the integrator is continuous.

End Notes

^aSee Definition 5 for the definition of a predictable process.

^bFor a proof of the fact that $\mathbb{D}_{\text{UCP}}$ is metrizable and complete under that metric, see [7].

^cThis sum converges to the *quadratic variation* of B over the interval $[0, t]$ as we see in Theorem 16.

Equivalence of Probability Measures

In finance it is often important to consider different probability measures. The statistical measure, commonly denoted by P , is supposed to (ideally) reflect the real-world dynamics of financial assets. A risk-neutral measure (see **Equivalent Martingale Measures**), often denoted by Q , is the measure of choice for the valuation of derivative securities. Prices of traded assets are supposed to be (local) Q -martingales, and hence their dynamics (as seen under Q) typically differs from their actual behavior (as modeled under P). How far can the dynamics with respect to these two measures be away in terms of qualitative behavior? We would not expect that events that do not occur in the real world, in the sense that they have P -probability zero, like a stock price exploding to infinity, would have positive Q -probability in the risk-neutral world. This discussion leads to the notion of absolute continuity.

Definition 1 Let P, Q be two probability measures defined on a measurable space $(\Omega, \mathcal{F})$. We say that Q is absolutely continuous with respect to P , denoted by $Q \ll P$, if all P -zero sets are also Q -zero sets. If $Q \ll P$ and $P \ll Q$ we say that P and Q are equivalent, denoted by $P \sim Q$. In other words, two equivalent measures have the same zero sets.

Let $Q \ll P$. By the Radon–Nikodym theorem there exists a density $Z = dQ/dP$ so that for $f \in L^1(Q)$ we can calculate its expectation with respect to Q by

$$E_Q[f] = E_P[Zf] \quad (1)$$

Note that if Q is absolutely continuous, but not equivalent to P , then we have $P(Z = 0) > 0$.

We now look at a dynamic picture, and assume that we also have a filtration $(\mathcal{F}_t)_{0 \leq t \leq T}$ at our disposal where T is some fixed finite time horizon. For $t \leq T$ let

$$Z_t = E_P[Z | \mathcal{F}_t] \quad (2)$$

We call the martingale $Z = (Z_t)$ the *density process* of Q . The *Bayes formula* tells us how to calculate conditional expectations with respect to Q in terms of P . Let $0 \leq s \leq t \leq T$ and f be $\mathcal{F}_t$ -measurable and

in $L^1(Q)$. We then have

$$Z_s E_Q[f | \mathcal{F}_s] = E_P[Z_t f | \mathcal{F}_s] \quad (3)$$

As consequence of Bayes' formula, we get that if M is a Q -martingale then ZM is a P -martingale and *vice versa*. Hence, we can turn any Q -martingale into a P -martingale by just multiplying it with the density process. It follows that the martingale property is *not* invariant under equivalent measure changes.

There are, however, a couple of important objects like stochastic integrals and quadratic variations which do remain invariant under equivalent measure changes although they depend, by their definition, *a priori* on some probability measure. Let us illustrate this in case of the quadratic variation of a semimartingale S . This is defined to be the limit in P -probability of the sum of the squared S -increments over a time grid, for vanishing mesh size. It is elementary that convergence in P -probability implies convergence in Q -probability if $Q \ll P$, and thus convergence in P -probability is equivalent to the convergence in Q -probability when P and Q are equivalent. This implies, for example, that quadratic variations remain the same under a change to an equivalent probability measure.

The compensator or angle bracket process, however, is *not* invariant with respect to equivalent measure changes. It is defined (for reasonable processes S) as the process $\langle S \rangle$ one has to subtract from the quadratic variation process $[S]$ to turn it into a local martingale. But, as we have seen, the martingale property typically gets lost by switching the measure. As an example, consider a Poisson process N with intensity λ . We have $[N] = N$, so the compensator equals λt . As we shall see below, the effect of an equivalent measure change is that the intensity changes as well, to μ , say, so the compensator under the new measure would be μt .

Girsanov's Theorem

As we have discussed above, the martingale property is not preserved under measure changes. Fortunately, it turns out that at least the semimartingale property is preserved. Moreover, it is possible to state the precise semimartingale decomposition under the new measure Q . This result is known in the literature as the *Girsanov's theorem*, although it was rather Cameron and Martin who proved a first version of

it in a Wiener space setting. Later on it was extended in various levels of generality by Girsanov, Meyer, and Lenglart, among many others.

Let us first give some examples. They are all the consequences of the general formulation of Girsanov's theorem to be given below.

1. Let B be a P -Brownian motion, $\mu \in \mathbb{R}$, and define an equivalent measure Q by the stochastic exponential

$$\frac{dQ}{dP} = \mathcal{E}(-\mu B)_T = \exp\left(-\mu B_T - \frac{1}{2}\mu^2 T\right) \quad (4)$$

Then $\widehat{B} = B + \mu t$ is a Q -Brownian motion (up to time T). Alternatively stated, the semimartingale decomposition of B under Q is $B = \widehat{B} - \mu t$. Hence the effect of the measure change is to add a drift term to the Brownian motion.

2. Let $N_t - \lambda t$ be a compensated Poisson process on an interval $[0, T]$ with P -intensity $\lambda > 0$, and let $\kappa > 0$. Define an equivalent measure Q by

$$\begin{aligned} \frac{dQ}{dP} &= e^{-\kappa\lambda T} \prod_{0 < s \leq T} (1 + \kappa \Delta N_s) \\ &= e^{-\kappa\lambda T} (1 + \kappa)^{N_T} \\ &= \exp(N_T \ln(1 + \kappa) - \kappa\lambda T) \end{aligned} \quad (5)$$

Then N is a Poisson process on $[0, T]$ under Q with intensity $(1 + \kappa)\lambda$. The process $N_t - (1 + \kappa)\lambda t$ is a compensated Poisson process under Q and thus a Q -martingale. Hence the effect of the measure change is to change the intensity of the Poisson process, or in other words, to add a drift term to the compensated Poisson process.

One of the most important applications of measure changes in mathematical finance is to find martingale measures for the price process S of some risky asset.

Definition 2 A martingale measure for S is a probability measure Q such that S is a Q -local martingale.

Let us now state a general form of Girsanov's theorem. It is not the most general setting, though, since we will assume that Q is equivalent to P which suffices for most applications in finance. This is due to the fact that one would often choose Q

to be a martingale measure for the price process, and then equivalence is a necessary condition to exclude arbitrage opportunities [1]. There is, however, also a result which covers the case where Q is only absolutely continuous, but not equivalent to P , and which has been proven by Lenglart [2].

Theorem 1 (Girsanov's Theorem: Standard Version). Let $P \sim Q$, with density process given by

$$Z_t = E\left[\frac{dQ}{dP} \middle| \mathcal{F}_t\right] \quad (6)$$

If S is a semimartingale under P with decomposition $S = M + A$ (here M is a local martingale, and A a process of locally finite variation), then S is a semimartingale under Q as well and has decomposition

$$\begin{aligned} S &= \left(M - \int \frac{1}{Z} d[Z, M]\right) \\ &\quad + \left(A + \int \frac{1}{Z} d[Z, M]\right) \end{aligned} \quad (7)$$

In particular, $M - \int \frac{1}{Z} d[Z, M]$ is a local Q -martingale.

In situations where the process S may exhibit jumps, it is often more convenient to apply a version of Girsanov which uses the angle bracket instead of the quadratic covariation.

Theorem 2 (Girsanov's Theorem: Predictable Version). Let $P \sim Q$, with density process as above, and $S = M + A$ be a P -semimartingale. Given that $\langle Z, M \rangle$ exists (with respect to P), then the decomposition of S under Q is

$$\begin{aligned} S &= \left(M - \int \frac{1}{Z_-} d\langle Z, M \rangle\right) \\ &\quad + \left(A + \int \frac{1}{Z_-} d\langle Z, M \rangle\right) \end{aligned} \quad (8)$$

Here Z_- denotes the left-continuous version of Z .

Whereas the standard version of Girsanov's theorem always works, we need an integrability condition (existence of $\langle Z, M \rangle$) for the predictable version.

However, in case $S = M + A$ for a local martingale M and a finite variation process A , it is rarely the case in a discontinuous framework that $dA \ll d[M]$, whereas it is quite natural in financial applications that $dA \ll d\langle M \rangle$ (see below).

In mathematical finance, these results are often applied to find a martingale measure for the price process S . Consider, for example, the Bachelier model where $S = B + \mu t$ is a Brownian motion plus drift. If we now take as above the measure change as given by a density process $Z_t = \exp\left(-\mu B_t - \frac{1}{2}\mu^2 t\right)$, then we have (since $dZ = -\mu Z dB$)

$$\begin{aligned} A + \int \frac{1}{Z} d[Z, M] &= \mu t + \int \frac{1}{Z} d\left[-\mu \int Z dB, B\right] \\ &= \mu t + \int \frac{1}{Z} d\left(-\mu \int Z dt\right) \\ &= 0 \end{aligned} \quad (9)$$

According to Girsanov's theorem (here the standard version coincides with the predictable one since S is continuous), the price process S is therefore a Q -local martingale (and, in fact, a Brownian motion according to Lévy's characterization), and hence Q is a martingale measure for S .

More generally, Girsanov's theorem implies an important structural result for the price process S in an arbitrage-free market. As has been mentioned above, it is essentially true that some no-arbitrage property implies the existence of an equivalent martingale measure Q for $S = M + A$, with density process Z . Therefore, we must have by the predictable version (8), given that $\langle Z, M \rangle$ exists, that

$$A = - \int \frac{1}{Z_-} d\langle Z, M \rangle \quad (10)$$

to get that S is a local Q -martingale. As it follows from the so-called Kunita-Watanabe inequality that

$$d\langle Z, M \rangle \ll d\langle M \rangle \quad (11)$$

(here $\langle Z, M \rangle$ respectively $\langle M \rangle$ are interpreted as the associated measures on the nonnegative real line), we conclude that

$$dA \ll d\langle M \rangle \quad (12)$$

and hence there exists some predictable process λ such that

$$S = M + \int \lambda d\langle M \rangle \quad (13)$$

For example, in the Bachelier model $S = B + \mu t$ we have that $\langle B \rangle_t = t$, and hence λ equals the constant μ .

The predictable version of Girsanov's theorem can now be applied to remove the drift $\int \lambda d\langle M \rangle$ as follows: we define a probability measure Q via

$$\frac{dQ}{dP} = \mathcal{E}\left(-\int \lambda dM\right)_T \quad (14)$$

where $\mathcal{E}$ denotes the Doléans-Dade stochastic exponential, assuming that $\mathcal{E}\left(-\int \lambda dM\right)$ is a martingale. The corresponding density process Z therefore satisfies the stochastic differential equation

$$dZ = -Z_- \lambda dM \quad (15)$$

It follows that

$$\langle Z, M \rangle = \left\langle -\int Z_- \lambda dM, M \right\rangle = -\int Z_- \lambda d\langle M \rangle \quad (16)$$

and

$$S = M + \int \lambda d\langle M \rangle = M - \int \frac{1}{Z_-} d\langle Z, M \rangle \quad (17)$$

is by the (predictable version) of the Girsanov theorem a local Q -martingale: the drift has been removed by the measure change.

This representation of S has an important consequence for the structure of martingale measures, provided the so-called *structure condition* holds:

$$\int_0^T \lambda_s^2 d\langle M \rangle_s < \infty \quad P\text{-a.s.} \quad (18)$$

In that case, the remarkable conclusion we can draw from (13) is that the existence of an equivalent martingale measure for S implies that S is a *special semimartingale*, for example, its finite variation part is predictable and therefore the semimartingale decomposition (13) is unique. Moreover, the following result holds.

Proposition 1 *Let Q be an equivalent martingale measure for S , and the structure condition (18) hold. Then the density process Z of Q with respect to P is given by the stochastic exponential*

$$Z = \mathcal{E}\left(-\int \lambda dM + L\right) \quad (19)$$

for some process L such that L as well as $[M, L]$ are local P -martingales. The converse statement is true as well, assuming that all involved processes are locally bounded: if Q is a probability measure whose density process can be written like in equation (19) with L as above, then Q is a martingale measure for S .

This result is fundamental in incomplete markets (see **Complete Markets**), where there are many equivalent martingale measures for the price process S . Indeed, any choice of L as in the statement of the proposition gives one particular pricing measure.

In applications in finance, the density process Z can also be interpreted in terms of a **change of numeraire**.

THORSTEN RHEINLÄNDER

Skorokhod Embedding

Analysis of a random evolution focuses initially on the behavior at a fixed deterministic, or random, time. The process and time horizon are known and we investigate the marginal law of the process. If we reverse this point of view, we face the embedding problem. We fix a probability distribution and a (well-understood) stochastic process and we try to design a random time such that the process at this time behaves according to the specified distribution. In other words, we know *what* we want to see and we ask *when* to look for it.

This *Skorokhod embedding problem* (SEP) or the *Skorokhod stopping problem*, first formulated and solved by A.V. Skorokhod in 1961 (English translation in 1965 [20]), is thus the problem of representing a given distribution μ as the distribution of a given stochastic process (such as a Brownian motion) at some stopping time. It has stimulated research in probability theory for over 40 years now—the problem has been changed, generalized, or specialized in various ways. We discuss some key results in the domain, along with the applications in quantitative finance, namely to the computation of robust market-consistent prices and hedges of exotic derivatives.

The Skorokhod Embedding Problem

The SEP problem can be stated as follows:

Given a stochastic process $(X_t : t \geq 0)$ and a probability measure μ , find a minimal stopping time τ such that X_τ has the law $\mu : X_\tau \sim \mu$.

At first, there seems to be a trivial solution to the SEP when $X_t = B_t$ is a Brownian motion. Write Φ and F_μ for the cumulative distribution function of the standard normal distribution and of μ , respectively. Then $F_\mu^{-1}(\Phi(B_1))$ has law μ and hence the stopping time $\tau = \inf\{t \geq 2 : B_t = F_\mu^{-1}(\Phi(B_1))\}$ satisfies $B_\tau \sim \mu$. However, this solution is intuitively “too large”, in particular $\mathbb{E}\tau = \infty$. A meaningful solution needs to be “small”. To express this, Skorokhod [20] imposed $\mathbb{E}\tau < \infty$ and solved the problem explicitly for any centered target measure with finite variance. To avoid the restriction on the set of target measures, in general, one requires τ to be *minimal*. Minimality of τ signifies that if a stopping time ρ satisfies $\rho \leq \tau$ and $X_\rho \sim X_\tau$ then $\rho = \tau$. When $\mathbb{E}B_\tau = 0$,

minimality of τ is equivalent to $(B_{t \wedge \tau} : t \geq 0)$ being a uniformly integrable martingale (see [6, 12]) and, in consequence, when $\mathbb{E}B_\tau^2 < \infty$, it is further equivalent to $\mathbb{E}\tau < \infty$. Note that we can have many, in fact, infinitely many, minimal stopping times all of which embed the same distribution μ .

We want τ to be “small” to enable us to iterate the embedding procedure. In this way, Skorokhod [20] represented a random walk as a Brownian motion stopped at an increasing sequence of stopping times and deduced properties of the random walk from the well-understood behavior of Brownian motion. As a simple example, one can use the representation to deduce the central limit theorem from the strong law of large numbers (cf. [14, Sec. 11.2]). The ideas of embedding processes into Brownian motion were extended and finally led to the celebrated work of Monroe [13], who proved that any semimartingale is a time-changed Brownian motion.

The SEP, as stated above, does not necessarily have a solution—existence of a solution depends greatly on X and μ . This can be seen already for real-valued diffusions [6]. However, for Brownian motion on $\mathbb{R}$, or any continuous local martingale (X_t) with $\langle X \rangle_\infty = \infty$ a.s., there is always a solution to the SEP and there are numerous explicit constructions (typically, for the case of centered μ), of which we give two examples below (cf. [14]).

Explicit Solutions

Skorokhod [20] and Dubins [8] solved the SEP for Brownian motion and arbitrary centered^a probability measure μ . However, the search for new solutions continued and was, to a large extent, motivated by the properties of the stopping times. Researchers sought simple explicit solutions that would have additional optimal properties. Several solutions were obtained using stopping times of the form

$$\tau = \inf\{t : (A_t, B_t) \in \Gamma\}, \quad \Gamma = \Gamma(\mu) \subset \mathbb{R}^2 \quad (1)$$

which is a first hitting time for the Markov process (A_t, B_t) , where (A_t) is some auxiliary increasing process. We now give two examples.

Consider $A_t = t$ and let τ_R be the resulting stopping time in (1). Root [17] proved that for any centered μ there is a *barrier* $\Gamma = \Gamma(\mu)$ such that $B_\tau \sim \mu$, where a *barrier* is a set in $\mathbb{R}_+ \times \mathbb{R}$ (time–space) such that if a point is in Γ , then all points to the right of it are also in Γ (see Figure 1).

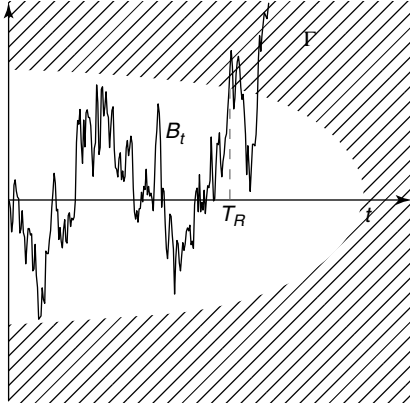

Figure 1 The barrier Γ and Root stopping time τ_R embedding a uniform law

Later Rost (cf. [14]) proved an analogous result replacing $\Gamma(\mu)$ with a reversed barrier $\tilde{\Gamma} = \tilde{\Gamma}(\mu)$, which is a set in time–space such that if a point is in $\tilde{\Gamma}$, then all the points to the left of it are also in $\tilde{\Gamma}$. We denote $\tilde{\tau}_R$ the first hitting of $\tilde{\Gamma}(\mu)$. Rost (cf. [14, 19]) proved that for any other solution τ to the SEP and any positive convex function f , we have

$$\mathbb{E}f(\tau_R) \leq \mathbb{E}f(\tau) \leq \mathbb{E}f(\tilde{\tau}_R) \quad (2)$$

In financial terms, as we will see, this implies bounds on the prices of volatility derivatives. Given a measure μ , the barrier Γ and the reversed barrier $\tilde{\Gamma}$ are not known explicitly. However, using techniques of partial differential equations, they can be computed numerically together with the bounds in equation (2) (see [9]).

Consider now $A_t = \bar{B}_t = \sup_{u \leq t} B_u$ in equation (1). Azéma and Yor [1] proved that, for a probability measure μ satisfying $\int x \mu(dx) = B_0$, the stopping time

$$\tau_{AY} = \inf\{t : \Psi_\mu(B_t) \leq \bar{B}_t\},$$

where
$$\Psi_\mu(x) = \frac{1}{\mu([x, \infty))} \int_{[x, \infty)} u \mu(du) \quad (3)$$

is minimal and $B_{\tau_{AY}} \sim \mu$. The Azéma–Yor stopping time is also optimal as it stochastically maximizes the maximum: $\mathbb{P}(\bar{B}_\tau \geq \alpha) \leq \mathbb{P}(\bar{B}_{\tau_{AY}} \geq \alpha)$, for all $\alpha \geq 0$ and any minimal τ with $B_\tau \sim \mu$. Later, Perkins [16] developed a stopping time τ_p , which, in turn, stochastically minimizes the maximum. As we will

see, these two solutions induce upper and lower bounds on the price of a one-touch option.

Applications

Robust Price Bounds

In the standard approach to pricing and hedging, one postulates a model for the underlying, calibrates it to the market prices of liquidly traded vanilla options (see **Call Options**), and then uses the model to derive prices and associated hedges for exotic over-the-counter products (such as **Barrier Options**; **Look-back Options**; **Foreign Exchange Options**). Prices and hedges will be correct only if the model describes the real world perfectly, which is not very likely. The SEP-driven approach uses the market data to deduce bounds on the prices consistent with *no-arbitrage* and the associated super-replicating strategies (see **Superhedging**), which are robust to model misspecification.

Assume *absence of arbitrage* (see **Fundamental Theorem of Asset Pricing**) and work under a risk-neutral measure (see **Risk-neutral Pricing**) so that the forward price process (see **Forwards and Futures**) $(S_t : t \leq T)$ is a martingale. Equivalently, under a simplifying assumption of zero interest rates, S_t is simply the stock price process. We are interested in pricing an exotic option with payoff given by a path-dependent functional $F(S)_T$. Our main example considered below is a *one-touch* option struck at α that pays 1 if the stock price reaches α before maturity T : $O^\alpha(S)_T = \mathbf{1}_{\bar{S}_T \geq \alpha}$, where $\bar{S}_T = \sup_{t \leq T} S_t$. It follows from Monroe's theorem that $S_t = B_{\rho_t}$, for a Brownian motion (B_t) with $B_0 = S_0$ and some increasing sequence of stopping times $\rho_t : t \leq T$ (possibly relative to an enlarged filtration). We make no other assumptions about the dynamics of the underlying. Instead, we propose to investigate the restrictions induced by the market data.

Suppose, first, that we know the market prices of calls and puts (see **Call Options**) for all strikes at one maturity T . This is equivalent to knowing the distribution μ of S_T (cf. [3]). Thus, we can see the stopping time $\rho = \rho_T$ as a solution to the SEP for μ . Conversely, given a solution τ to the SEP for μ , the process $\tilde{S}_t = B_{\tau \wedge \frac{t}{T-\tau}}$ is a model for the stock-price process consistent with the observed prices of calls and puts at maturity T . In this way, we obtain

a correspondence that allows us to identify market models with solutions to the SEP and *vice versa*. In consequence, to estimate the fair price of the exotic option $\mathbb{E}F(S)_T$, it suffices to bound $\mathbb{E}F(B)_\tau$ among all solutions τ to the SEP. More precisely, if $F(S)_T = F(B)_{\rho_T}$ a.s., then we have

$$\inf_{\tau: B_\tau \sim \mu} \mathbb{E}F(B)_\tau \leq \mathbb{E}F(S)_T \leq \sup_{\tau: B_\tau \sim \mu} \mathbb{E}F(B)_\tau \quad (4)$$

where all stopping times τ are minimal. Consider, for example, a volatility derivative^b paying $F(S)_T = f(\langle S \rangle_T)$, for some positive convex function f , and suppose that the underlying (S_t) is continuous. Then, by Dubins–Schwarz theorem, we can take the time change $\rho_t = \langle S \rangle_t$ so that $f(\langle S \rangle_T) = f(\rho_T) = F(B)_{\rho_T}$. Using inequality (2), inequality (4) becomes

$$\mathbb{E}f(\tau_R) \leq \mathbb{E}f(\langle S \rangle_T) \leq \mathbb{E}f(\tilde{\tau}_R) \quad (5)$$

where $B_{\tau_R} \sim S_T \sim B_{\tilde{\tau}_R}$ (cf. [9]).

When (S_t) has jumps typically one of the bounds in inequality (4) remains true and the other degenerates. In the example of a one-touch option, one sees that $O^\alpha(S)_T \leq O^\alpha(B)_{\rho_T}$ and the fair price is always bounded above by $\sup_\tau \{\mathbb{P}(\bar{B}_\tau \geq \alpha) : B_\tau \sim \mu\}$. Furthermore, the supremum is attained by the Azéma–Yor construction discussed above. The best lower bound on the price in the presence of jumps is the obvious bound $\mu([\alpha, \infty))$. In consequence, the price of a one-touch option $\mathbb{E}O^\alpha(S)_T = \mathbb{P}(\bar{S}_T \geq \alpha)$ is bounded by

$$\begin{aligned} \mu([\alpha, \infty)) &\leq \mathbb{P}(\bar{S}_T \geq \alpha) \leq \mathbb{P}(\bar{B}_{\tau_{AY}} \geq \alpha) \\ &= \mu([\Psi_\mu^{-1}(\alpha))) \end{aligned} \quad (6)$$

and the lower bound can be improved to $\mathbb{P}(\bar{B}_{\tau_P} \geq \alpha)$ under the hypothesis that (S_t) is continuous, where τ_P is Perkins' stopping time (see [5] for detailed discussion and numerical examples). Selling a one-touch option for a lower price than the upper bound in equation (6) necessarily involves some risk. If additional modeling assumptions are made, then a lower price can be justified, but this new price is not necessarily robust to model misspecification.

The above analysis can be extended if we know more market data. For example, knowing prices of puts and calls at some earlier expiry $T_1 < T$ would lead to solving the SEP, constrained by embedding an intermediate law μ_1 before μ . This was achieved by Brown *et al.* [4] who gave an explicit construction

of an embedding that maximizes the maximum. As we have seen, in financial terms, this amounts to obtaining the least upper bound on the price of a one-touch option.

In practice, we do not observe the prices of calls and puts for all strikes but only for a finite family of strikes. As a result, the terminal law of S_T is not specified entirely and one needs to optimize among possible terminal laws (cf. [5, 10]). In general, different sets of market prices lead to embedding problems with different constraints. The resulting problems can be complex. In particular, to our best knowledge, there are no known optimal solutions to the SEP with multiple intermediate law constraints.

Robust Hedging

Once we know the price-range for an option, we want to understand model-free super-replicating strategies (see **Superhedging**). In general, to achieve this, we need to develop a pathwise approach to the SEP. Following [5], we treat the example of a one-touch option. We develop a super-replicating portfolio with the initial wealth equal to the upper bound displayed in equation (6).

The key observation lies in the following simple inequality:

$$\mathbf{1}_{\bar{S}_T \geq \alpha} \leq \frac{(S_T - K)^+}{\alpha - K} + \frac{S_{\bar{S} \wedge T} - S_T}{\alpha - K} \mathbf{1}_{\bar{S}_T \geq \alpha} \quad (7)$$

where $\alpha > S_0, K$ and $\bar{S} = \inf\{t : S_t \geq \alpha\}$. Taking expectations yields $\mathbb{P}(\bar{S}_T \geq \alpha) \leq C(K)/(\alpha - K)$, where $C(K)$ denotes the price of a European call with strike K and maturity T . Taking the optimal $K = K^*$ such that $C(K^*) = (\alpha - K^*)|C'(K^*)|$ we find $\mathbb{P}(\bar{S}_T \geq \alpha) \leq |C'(K^*)| = \mathbb{P}(S_T \geq K^*)$. On the other hand, using $|C'(K)| = \mu([K, \infty))$, where $\mu \sim S_T$, we have

$$C(K) = \int_K^\infty (u - K)\mu(du) = |C'(K)|(\Psi_\mu(K) - K) \quad (8)$$

The equation for K^* implies readily that $K^* = \Psi_\mu^{-1}(\alpha)$ and the bound we have derived coincides with equation (6).

Inequality (7) encodes the super-replicating strategy. The first term of the right-hand side means we buy $1/(\alpha - K^*)$ calls with strike K^* . The second

term is a simple dynamic trading: if the price reaches level α , we sell $1/(\alpha - K^*)$ forwards on the stock. At the cost of $C_1 = C(K^*)/(\alpha - K^*)$ we are then guaranteed to super-replicate the one-touch regardless of the dynamics of the underlying. In consequence, selling the one-touch for $C_2 > C_1$ would be an arbitrage opportunity as we would make a riskless profit of $C_2 - C_1$. Finally, note that our derivation of the superhedge is pathwise and makes no assumptions about the existence (or uniqueness) of the pricing measure.

Other Resources

The arguments for robust pricing and hedging of lookback (see **Lookback Options**) and barrier (see **Barrier Options**) options can be found in the pioneering work of Hobson [10] and in [5]. Dupire [9] investigated volatility derivatives using the SEP. Cox *et al.* [7] designed pathwise inequalities to derive price range and robust super-replicating strategies for derivatives paying a convex function of the local time (see **Local Times; Corridor Variance Swap**). The idea of *no-arbitrage* bounds on the prices goes back to Merton [11] (see **Arbitrage Bounds**). This was refined in *no-good deals* (see **Good-deal Bounds**) pricing, where one postulates that markets not only exclude arbitrage opportunities but also any *highly desirable investments*. *No-good deals* pricing yields tighter bounds on the prices but requires an arbitrary choice of utility function.

We refer to [14] for an extended survey of the SEP, including its history and overview of its applications. We have not discussed here the SEP for processes other than Brownian motion. Rost [18] investigated the problem for a general Markov process and has a necessary and sufficient condition on the target measure μ for existence of an embedding. Bertoin and Le Jan [2] then developed an explicit solution, in a broad class of Markov processes, which was based on additive functionals. More recently, the approach of Vallois [21] was extended to provide explicit solutions for classes of discontinuous processes including Azéma's martingale [15].

Markov Processes

A *Markov process* is a process that evolves in a memoryless way: its future law depends on the past only through the present position of the process. This property can be formalized in terms of conditional expectations: a process $(X_t, t \geq 0)$ adapted to the **filtration** $(\mathcal{F}_t)_{t \geq 0}$ (representing the information available at time t) is a Markov process if

$$\mathbb{E}(f(X_{t+s}) \mid \mathcal{F}_t) = \mathbb{E}(f(X_{t+s}) \mid X_t) \quad (1)$$

for all $s, t \geq 0$ and f bounded and measurable.

The interest of such a process in financial models becomes clear when one observes that the price of an option, or more generally, the value at time t of any future claim with maturity T , is given by the general formula (see **Risk-neutral Pricing**)

$$\begin{aligned} V_t &= \text{value at time } t \\ &= \mathbb{E}(\text{discounted payoff at time } T \mid \mathcal{F}_t) \end{aligned} \quad (2)$$

where the expectation is computed with respect to a *pricing measure* (see **Equivalent Martingale Measures**). The Markov property is a frequent assumption in financial models because it provides powerful tools (semigroup, theory of partial differential equations (PDEs), etc.) for the quantitative analysis of such problems.

Assuming the Markov property (1) for $(S_t, t \geq 0)$, the value V_t of the option can be expressed as

$$\begin{aligned} V_t &= \mathbb{E}(e^{-r(T-t)} f(S_T) \mid \mathcal{F}_t) \\ &= \mathbb{E}(e^{-r(T-t)} f(S_T) \mid S_t) \end{aligned} \quad (3)$$

so V_t can be expressed as a (deterministic) function of t, S_t : $u(t, S_t) = \mathbb{E}(e^{-r(T-t)} f(S_T) \mid S_t)$. Furthermore, this function u is shown to be the solution of a parabolic PDE, the Kolmogorov backward equation.

The goal of this article is to present the Markov processes and their relation with PDEs, and to illustrate the role of Markovian models in various financial problems. We give a general overview of the links between Markov processes and PDEs without giving more details and we focus on the case of Markov processes solution to stochastic differential equations (SDEs).

We will restrict ourselves to $\mathbb{R}^d$ -valued Markov processes. The set of Borel subsets of $\mathbb{R}^d$ is denoted

by $\mathcal{B}$. In the following, we will denote a Markov process by $(X_t, t \geq 0)$, or simply X when no confusion is possible.

Markov Property and Transition Semigroup

A Markov process retains no memory of where it has been in the past. Only the current state of the process influences its future dynamics. The following definition formalizes this notion:

Definition 1 *Let $(X_t, t \geq 0)$ be a stochastic process defined on a probability filtered space $(\Omega, \mathcal{F}_t, \mathbb{P})$ with values in $\mathbb{R}^d$. X is a Markov process if*

$$\mathbb{P}(X_{t+s} \in \Gamma \mid \mathcal{F}_t) = \mathbb{P}(X_{t+s} \in \Gamma \mid X_t) \quad \mathbb{P}\text{-a.s.} \quad (4)$$

for all $s, t \geq 0$ and $\Gamma \in \mathcal{B}$. Equation (4) is called the *Markov property* of the process X . The Markov process is called *time homogeneous* if the law of X_{t+s} conditionally on $X_t = x$ is independent of t .

Observe that equation (4) is equivalent to equation (1) and that X is a time-homogeneous Markov process if there exists a positive function P defined on $\mathbb{R}_+ \times \mathbb{R}^d \times \mathcal{B}$ such that

$$P(s, X_t, \Gamma) = \mathbb{P}(X_{t+s} \in \Gamma \mid \mathcal{F}_t) \quad (5)$$

holds $\mathbb{P}$ -a.s. for all $t, s \geq 0$ and $\Gamma \in \mathcal{B}$. P is called the *transition function* of the time homogeneous Markov process X .

For the moment, we restrict ourselves to the time-homogeneous case.

Proposition 1 *The transition function P of a time-homogeneous Markov process X satisfies*

1. $P(t, x, \cdot)$ is a probability measure on $\mathbb{R}^d$ for any $t \geq 0$ and $x \in \mathbb{R}^d$,
2. $P(0, x, \cdot) = \delta_x$ (unit mass at x) for any $x \in \mathbb{R}^d$,
3. $P(\cdot, \cdot, \Gamma)$ is measurable for any $\Gamma \in \mathcal{B}$, and for any $s, t \geq 0, x \in \mathbb{R}^d, \Gamma \in \mathcal{B}$, P satisfies the Chapman–Kolmogorov property

$$P(t+s, x, \Gamma) = \int_{\mathbb{R}^d} P(s, y, \Gamma) P(t, x, dy) \quad (6)$$

From an analytical viewpoint, we can think of the transition function as a Markov semigroup^a $(P_t, t \geq 0)$, defined by

$$\begin{aligned} P_t f(x) &:= \int_{\mathbb{R}^d} P(t, x, dy) f(dy) \\ &= \mathbb{E}(f(X_t) \mid X_0 = x) \end{aligned} \quad (7)$$

in which case the Chapman–Kolmogorov equation becomes the *semigroup property*

$$P_s P_t = P_{t+s}, \quad s, t \geq 0 \quad (8)$$

Conversely, given a Markov semigroup $(P_t, t \geq 0)$ and a probability measure ν on $\mathbb{R}^d$, it is always possible to construct a Markov process X with initial law ν that satisfies equation (7) (see [9, Th.4.1.1]). The links between PDEs and Markov processes are based on this equivalence between semigroups and Markov processes. This can be expressed through a single object: the infinitesimal generator.

Strong Markov Property, Feller Processes

Recall that a random time τ is called a $\mathcal{F}_t$ -*stopping time* if $\{\tau \leq t\} \in \mathcal{F}_t$ for any $t \geq 0$.

Definition 2 A Markov process $(X_t, t \geq 0)$ with transition function $P(t, x, \Gamma)$ is *strong Markov* if, for any $\mathcal{F}_t$ -stopping time τ ,

$$\mathbb{P}(X_{\tau+t} \in \Gamma \mid \mathcal{F}_\tau) = P(t, X_\tau, \Gamma) \quad (9)$$

for all $t \geq 0$ and $\Gamma \in \mathcal{B}$.

Let $C_0(\mathbb{R}^d)$ denote the space of bounded continuous functions on $\mathbb{R}^d$, which vanish at infinity, equipped with the L^∞ norm denoted by $\|\cdot\|$.

Definition 3 A Feller semigroup^b is a strongly continuous,^c positive, Markov semigroup $(P_t, t \geq 0)$ such that $P_t : C_0(\mathbb{R}^d) \rightarrow C_0(\mathbb{R}^d)$ and

$$\begin{aligned} \forall f \in C_0(\mathbb{R}^d), \quad 0 \leq f &\Rightarrow 0 \leq P_t f \\ \forall f \in C_0(\mathbb{R}^d) \quad \forall x \in \mathbb{R}^d, \quad P_t f(x) &\rightarrow f(x) \text{ as } t \rightarrow 0 \end{aligned} \quad (10)$$

For a Feller semigroup, the corresponding Markov process can be constructed as a strong Markov process.

Theorem 1 ([9] Th.4.2.7). *Given a Feller semigroup $(P_t, t \geq 0)$ and any probability measure ν on $\mathbb{R}^d$, there exists a filtered probability space $(\Omega, \mathcal{F}_t, \mathbb{P})$ and a strong Markov process $(X_t, t \geq 0)$ on this space with values in $\mathbb{R}^d$ with initial law ν and with transition function P_t . A strong Markov process whose semigroup is Feller is called a Feller process.*

Infinitesimal Generator

We are now in a position to introduce the key notion of *infinitesimal generator* of a Feller process.

Definition 4 For a Feller process $(X_t, t \geq 0)$, the *infinitesimal generator* of X is the (generally unbounded) linear operator $L : \mathcal{D}(L) \rightarrow C_0(\mathbb{R}^d)$ defined as follows. We write $f \in \mathcal{D}(L)$ if, for some $g \in C_0(\mathbb{R}^d)$, we have

$$\frac{\mathbb{E}(f(X_t) \mid X_0 = x) - f(x)}{t} \rightarrow g(x) \quad (11)$$

when $t \rightarrow 0$ for the norm $\|\cdot\|$, and we then define $Lf = g$.

By Theorem 1, an equivalent definition can be obtained by replacing X by its Feller semigroup $(P_t, t \geq 0)$. In particular, for all $f \in \mathcal{D}(L)$,

$$Lf(x) = \lim_{t \rightarrow 0} \frac{P_t f(x) - f(x)}{t} \quad (12)$$

An important property of the infinitesimal generator is that it allows one to construct fundamental martingales associated with a Feller process.

Theorem 2 ([21], III.10). *Let X be a Feller process on $(\Omega, \mathcal{F}_t, \mathbb{P})$ with infinitesimal generator L such that $X_0 = x \in \mathbb{R}^d$. For all $f \in \mathcal{D}(L)$,*

$$f(X_t) - f(x) - \int_0^t Lf(X_s) ds \quad (13)$$

defines a $\mathcal{F}_t$ -martingale. In particular,

$$\mathbb{E}(f(X_t)) = f(x) + \mathbb{E}\left(\int_0^t Lf(X_s) ds\right) \quad (14)$$

As explained earlier, the law of a Markov process is characterized by its semigroup. In most cases, a Feller semigroup can be itself characterized by its infinitesimal generator (the precise conditions for

this to hold are given by the Hille–Yosida theorem, see [21, Th.III.5.1]). For almost all Markov financial models, these conditions are well established and always satisfied (see Examples 1, 2, 3, and 4). As illustrated by equation (14), when $\mathcal{D}(L)$ is large enough, the infinitesimal generator captures the law of the whole dynamics of a Markov process and provides an analytical tool to study the Markov process. The other major mathematical tool used in finance is the stochastic calculus (see **Stochastic integral**, **Itô formula**), which applies to **Semimartingales** (see [18]). It is therefore crucial for applications to characterize under which conditions a Markov process is a semimartingale. This question is answered for very general processes in [5]. We mention that this is always the case for Feller diffusions, defined later.

Feller Diffusions

Let us consider the particular case of continuous Markov processes, which include the solutions of stochastic differential equations (SDEs).

Definition 5 A Feller diffusion on $\mathbb{R}^d$ is a Feller process X on $\mathbb{R}^d$ that has continuous paths, and such that the domain $\mathcal{D}(L)$ of the generator L of X contains the space $C_K^\infty(\mathbb{R}^d)$ of infinitely differentiable functions of compact support.

Feller diffusions are Markov processes admitting a second-order differential operator as infinitesimal generator.

Theorem 3 For any $f \in C_K^\infty(\mathbb{R}^d)$, the infinitesimal generator L of a Feller diffusion has the form

$$Lf(x) = \frac{1}{2} \sum_{i,j=1}^d a_{ij}(x) \frac{\partial^2 f}{\partial x_i \partial x_j}(x) + \sum_{i=1}^d b_i(x) \frac{\partial f}{\partial x_i}(x) \quad (15)$$

where the functions $a_{ij}(\cdot)$ and $b_i(\cdot)$, $1 \leq i, j \leq d$ are continuous and the matrix $a = (a_{ij}(x))_{1 \leq i, j \leq d}$ is nonnegative definite symmetric for all $x \in \mathbb{R}^d$.

Kolmogorov Equations

Observe by equation (12) that the semigroup P_t of a Feller process X satisfies the following differential

equation; for all $f \in \mathcal{D}(L)$,

$$\frac{d}{dt} P_t f = L P_t f \quad (16)$$

This equation is called *Kolmogorov's backward equation*. In particular, if L is a differential operator (e.g., if X is a Feller diffusion), the function $u(t, x) = P_t f(x)$ is the solution of the PDE

$$\begin{cases} \frac{\partial u}{\partial t} = Lu \\ u(0, x) = f(x) \end{cases} \quad (17)$$

Conversely, if this PDE admits a unique solution, then its solution is given by

$$u(t, x) = \mathbb{E}(f(X_t) \mid X_0 = x) \quad (18)$$

This is the simplest example of a probabilistic interpretation of the solution of a PDE in terms of a Markov process.

Moreover, because Feller semigroups are strongly continuous, it is easy to check that the operators P_t and L commute. Therefore, equation (16) may be rewritten as

$$\frac{d}{dt} P_t f = P_t L f \quad (19)$$

This equation is known as Kolmogorov's forward equation. It is the weak formulation of the equation

$$\frac{d}{dt} \mu_t^x = L^* \mu_t^x \quad (20)$$

where the probability measure μ_t^x on $\mathbb{R}^d$ denotes the law of X_t conditioned on $X_0 = x$ and where L^* is the adjoint operator of L . In particular, with the notation of Theorem 3, if X is a Feller diffusion and if $\mu_t^x(dy)$ admits a density $q(x; t, y)$ with respect to Lebesgue's measure on $\mathbb{R}^d$ (which holds, e.g., if the functions $b_i(x)$ and $a_{ij}(x)$ are bounded and locally Lipschitz, if the functions $a_{ij}(x)$ are globally Hölder and if the matrix $a(x)$ is uniformly positive definite [10, Th.6.5.2]), the forward Kolmogorov equation is the weak form (in the sense of the distribution theory) of the PDE

$$\begin{aligned} \frac{\partial}{\partial t} q(x; t, y) = & - \sum_{i=1}^d \frac{\partial}{\partial y_i} (b_i(y) q(x; t, y)) \\ & + \sum_{i,j=1}^d \frac{\partial^2}{\partial y_i \partial y_j} (a_{ij}(y) q(x; t, y)) \end{aligned} \quad (21)$$

This equation is known as *Fokker–Planck equation* and gives another family of PDEs that have probabilistic interpretations. Fokker–Planck equation has applications in finance for quantiles, Value at Risk, or risk measure computations [22], whereas Kolmogorov’s backward equation (17) is more suited to financial problems related to the hedging of derivatives products or portfolio allocation (see the section “Parabolic PDEs Associated to Markov Processes”, and sequel).

Time-inhomogeneous Markov Processes

The law of a time-inhomogeneous Markov process is described by the doubly indexed family of operators $(P_{s,t}, 0 \leq s \leq t)$ where, for any bounded measurable f and any $x \in \mathbb{R}^d$,

$$P_{s,t}f(x) = \mathbb{E}(f(X_t) \mid X_s = x) \quad (22)$$

Then, the semigroup property becomes, for $s \leq t \leq r$,

$$P_{s,t}P_{t,r} = P_{s,r} \quad (23)$$

Definition 3 of Feller semigroups can be generalized to time-inhomogeneous processes as follows. The time-inhomogeneous Markov process X is called a *Feller time-inhomogeneous process* if $(P_{s,t}, 0 \leq s \leq t)$ is a family of positive, Markov linear operators on $C_0(\mathbb{R}^d)$ which is strongly continuous in the sense

$$\forall s \geq 0, \quad x \in \mathbb{R}^d, f \in C_0(\mathbb{R}^d), \quad \|P_{s,t}f - f\| \rightarrow 0 \quad (24)$$

as $t \rightarrow s$

In this case, it is possible to generalize the notion of infinitesimal generator. For any t , let

$$\begin{aligned} L_t f(x) &= \lim_{s \rightarrow 0} \frac{P_{t,t+s}f(x) - f(x)}{s} \\ &= \lim_{s \rightarrow 0} \frac{\mathbb{E}[f(X_{t+s}) \mid X_t = x] - f(x)}{s} \end{aligned} \quad (25)$$

for any $f \in C_0(\mathbb{R}^d)$ such that $L_t f \in C_0(\mathbb{R}^d)$ and the limit above holds in the sense of the norm $\|\cdot\|$. The set of such $f \in C_0(\mathbb{R}^d)$ is called the *domain* $\mathcal{D}(L_t)$ of the operator L_t . $(L_t, t \geq 0)$ is called the *family of*

time-inhomogeneous infinitesimal generators of the process X .

All the results on Feller processes stated earlier can be easily transposed to the time-inhomogeneous case, observing that if $(X_t, t \geq 0)$ is a time-inhomogeneous Markov process on $\mathbb{R}^d$, then $(\tilde{X}_t, t \geq 0)$, where $\tilde{X}_t = (t, X_t)$ is a time-homogeneous Markov process on $\mathbb{R}_+ \times \mathbb{R}^d$. Moreover, if X is time-inhomogeneous Feller, it is elementary to check that the process $\tilde{X}$ is time-homogeneous Feller as defined in Definition 3. Its semigroup $(\tilde{P}_t, t \geq 0)$ is linked to the time-inhomogeneous semigroup by the relation

$$\begin{aligned} \tilde{P}_t f(s, x) &= \mathbb{E}[f(s+t, X_{s+t}) \mid X_s = x] \\ &= (P_{s,s+t}f(s+t, \cdot))(x) \end{aligned} \quad (26)$$

for all bounded and measurable $f : \mathbb{R}_+ \times \mathbb{R}^d \rightarrow \mathbb{R}$. If $\tilde{L}$ denotes the infinitesimal generator of the process $\tilde{X}$, it is elementary to check that, for any $f(t, x) \in \mathcal{D}(\tilde{L})$ that is differentiable with respect to t , with derivative uniformly continuous in (t, x) , $x \mapsto f(t, x)$ belongs to $\mathcal{D}(L_t)$ for any $t \geq 0$ and

$$\tilde{L}f(t, x) = \frac{\partial f}{\partial t}(t, x) + (L_t f(t, \cdot))(x) \quad (27)$$

On this observation, it is possible to apply Theorem 3 to time-inhomogeneous Feller diffusions, defined as continuous time-inhomogeneous Feller processes with infinitesimal generators $(L_t, t \geq 0)$ such that $C_K^\infty(\mathbb{R}^d) \subset \mathcal{D}(L_t)$ for any $t \geq 0$. For such processes, there exist continuous functions b_i and a_{ij} , $1 \leq i, j \leq d$ from $\mathbb{R}_+ \times \mathbb{R}^d$ to $\mathbb{R}$ such that the matrix $a(t, x) = (a_{i,j}(t, x))_{1 \leq i, j \leq d}$ is symmetric nonnegative definite and

$$\begin{aligned} L_t f(x) &= \frac{1}{2} \sum_{i,j=1}^d a_{ij}(t, x) \frac{\partial^2 f}{\partial x_i \partial x_j}(x) \\ &\quad + \sum_{i=1}^d b_i(t, x) \frac{\partial f}{\partial x_i}(x) \end{aligned} \quad (28)$$

for all $t \geq 0$, $x \in \mathbb{R}^d$ and $f \in C_K^\infty(\mathbb{R}^d)$.

For more details on time-inhomogeneous Markov processes, we refer to [10].

Example 1 Brownian Motion The standard one-dimensional Brownian motion $(B_t, t \geq 0)$ is a Feller diffusion in $\mathbb{R}$ ($d = 1$) such that $B_0 = 0$ and for

which the parameters of Theorem 3 are $b = 0$ and $a = 1$. The Brownian motion is the fundamental prototype of Feller diffusions. Other diffusions are inherited from this process because they can be expressed as solutions to SDEs driven by independent Brownian motions (see later). Similarly, the standard d -dimensional Brownian motion is a vector of d independent standard one-dimensional Brownian motions and corresponds to the case $b_i = 0$ and $a_{ij} = \delta_{ij}$ for $1 \leq i, j \leq d$, where δ_{ij} is the Kronecker delta function ($\delta_{ij} = 1$ if $i = j$ and 0 otherwise).

Example 2 Black–Scholes Model In the Black–Scholes model, the underlying asset price S_t follows a geometric Brownian motion with constant drift μ and volatility σ .

$$S_t = S_0 \exp((\mu - \sigma^2/2)t + \sigma B_t) \quad (29)$$

where B is a standard Brownian motion. With Itô's formula, it is easily checked that S is a Feller diffusion with infinitesimal generator

$$Lf(x) = \mu x f'(x) + \frac{1}{2} \sigma^2 x^2 f''(x) \quad (30)$$

Itô's formula also yields

$$S_t = S_0 + \mu \int_0^t S_s ds + \sigma \int_0^t S_s dB_s \quad (31)$$

which can be written as the SDE

$$dS_t = \mu S_t dt + \sigma S_t dB_t \quad (32)$$

The correspondence between the SDE and the second-order differential operator L appears below as a general fact.

Example 3 Stochastic Differential Equations SDEs are probably the most used Markov models in finance. Solutions of SDEs are examples of Feller diffusions. When the parameters b_i and a_{ij} of Theorem 3 are sufficiently regular, a Feller process X with generator equation (15) can be constructed as the solution of the SDE

$$dX_t = b(X_t)dt + \sigma(X_t)dB_t \quad (33)$$

where $b(x) \in \mathbb{R}^d$ is $(b_1(x), \dots, b_d(x))$, where the $d \times r$ matrix $\sigma(x)$ satisfies $a_{ij}(x) = \sum_{k=1}^r \sigma_{ik}(x)\sigma_{jk}(x)$

(i.e., $a = \sigma\sigma'$) and where B_t is a r -dimensional standard Brownian motion. For example, when $d = r$, one can take for $\sigma(x)$ the symmetric square root matrix of the matrix $a(x)$.

The construction of Markov solutions to the SDE (33) with generator (15) is possible if b and σ are globally Lipschitz with linear growth [13, Th.5.2.9], or if b and a are bounded and continuous functions [13, Th.5.4.22]. In the second case, the SDE has a solution in a weaker sense. Uniqueness (at least in law) and the strong Markov property hold if b and σ are locally Lipschitz [13, Th.5.2.5], or if b and a are Hölder continuous and the matrix a is uniformly positive definite [13, Rmk.5.4.30, Th.5.4.20]. In the one-dimensional case, existence and uniqueness for the SDE (32) can be proved under weaker assumptions [13, Sec.5.5].

In all these cases, the Markov property allows one to identify the SDE (33) with its generator (15). This will allow us to make the link between parabolic PDEs and the corresponding SDE in the section “Parabolic PDEs Associated to Markov Processes” and sequel.

Similarly, one can associate to the time-inhomogeneous SDE

$$dX_t = b(t, X_t)dt + \sigma(t, X_t)dB_t \quad (34)$$

the time-inhomogeneous generators (28). Existence for this SDE holds if b_t and σ_{ij} are globally Lipschitz in x and locally bounded (uniqueness holds if b_t and σ_{ij} are only locally Lipschitz in x). As earlier, in this case, a solution to equation (34) is strong Markov. We refer the reader to [16] for more details.

Example 4 Backward Stochastic Differential Equations Backward stochastic differential equations are SDEs where a random variable is given as a terminal condition. Let us motivate the definition of a backward SDE (BSDE) by continuing the study of the elementary example of the introduction of this article.

Consider an asset S_t modeled by the Black–Scholes SDE (32) and assume that it is possible to borrow and lend cash at a constant risk-free interest rate r . A self-financed trading strategy is determined by an initial portfolio value and the amount π_t of the portfolio value placed in the risky asset at time t . Given the stochastic process $(\pi_t, t \geq 0)$, the portfolio

value V_t at time t solves the SDE

$$dV_t = rV_t dt + \pi_t(\mu - r) dt + \sigma\pi_t dB_t \quad (35)$$

where B is the Brownian motion driving the dynamics (32) of the risky asset S .

Assume that this portfolio serves to hedge a call option with strike K and maturity T . This problem can be expressed as finding a couple of processes (V_t, π_t) adapted to the Brownian filtration $\mathcal{F}_t = \sigma(B_s, s \leq t)$ such that

$$V_t = (S_T - K)^+ - \int_t^T (rV_s + \pi_s(\mu - r)) ds - \int_t^T \sigma\pi_s dB_s \quad (36)$$

Such SDEs with terminal condition and with unknown process driving the Brownian integral are called *BSDEs*. This particular BSDE admits a unique solution (see the section “Quasi- and Semilinear PDEs and BSDEs”) and can be explicitly solved. Because V_0 is $\mathcal{F}_0$ adapted, it is nonrandom and therefore V_0 is the usual free arbitrage price of the option. In particular, choosing $\mu = r$, we recover the usual formula for the free arbitrage price $V_0 = \mathbb{E}[e^{-rT}(S_T - K)^+]$, and the quantity of risky asset π_t/S_t in the portfolio is given by the Black–Scholes Δ -hedge $\partial u / \partial x(t, S_t)$, where $u(t, x)$ is the solution of the Black–Scholes PDE (see **Exchange Options**)

$$\begin{cases} \frac{\partial u}{\partial t} + rx \frac{\partial u}{\partial x} + \frac{\sigma^2}{2} x^2 \frac{\partial^2 u}{\partial x^2} - ru = 0 \\ \quad \forall (t, x) \in [0, T) \times (0, +\infty) \\ u(T, x) = f(x) \quad \forall x \in (0, +\infty) \end{cases} \quad (37)$$

Applying Itô formula to $u(t, S_t)$, an elementary computation shows that $u(t, S_t)$ solves the same SDE (35) with $\mu = r$ as V_t , with the same terminal condition. Therefore, by uniqueness, $V_t = u(t, S_t)$.

Usually, for more general BSDEs, $(\pi_t, t \geq 0)$ is an implicit process given by the martingale representation theorem. In the section “Quasi- and Semilinear PDEs and BSDEs”, we give results on the existence and uniqueness of solutions of BSDEs, and on their links with nonlinear PDEs.

Discontinuous Markov Processes

In financial models, it is sometimes natural to consider discontinuous Markov processes, for example, when one wants to take into account jumps in prices. This can sometimes be done by modeling the dynamics using **Poisson processes**, **Lévy processes** or other jump processes (see **Jump Processes**). In particular, it is possible to define SDEs where the Brownian motion is replaced by a Lévy process (see **CGMY model**, **NIG model**, or **Generalized hyperbolic model** for examples). In this situation, the generator is an integro-differential operator and the parabolic PDE is replaced by **Partial integro-differential Equations**.

Dimension of the State Space

In many pricing/hedging problems, the dimension of the pricing PDE is greater than the state space of the underlyings. In such cases, the financial problem is apparently related to non-Markov stochastic processes. However, it can usually be expressed in terms of Markov processes if one increases the dimension of the process considered. For example, in the context of Markov **short rates** $(r_t, t \geq 0)$, the pricing of a **zero-coupon bond** is expressed in terms of the process $R_t = \int_0^t r_s ds$ which is not Markovian, whereas the couple (r_t, R_t) is Markovian. For **Asian options** on a Markov asset, the couple formed by the asset and its integral is Markovian. If the asset involves a stochastic volatility solution to a SDE (see **Heston model** and **SABR model**), then the couple formed by the asset value and its volatility is Markov. As mentioned earlier, another important example is given by time-inhomogeneous Markov processes that become time homogeneous when one considers the couple formed by the current time and the original process.

In some cases, the dimension of the system can be reduced while preserving the Markovian nature of the problem. In the case of the portfolio management of multidimensional Black–Scholes prices with deterministic volatility matrix, mean return vector and interest rate, the dimension of the problem is actually reduced to one (see **Merton problem**). When the volatility matrix, the mean return vector, and the interest rate are Markov processes of dimension d' , the dimension of the problem is reduced to $d' + 1$.

Parabolic PDEs Associated to Markov Processes

Computing the value of any future claim with fixed maturity (for example, the price of an European option on an asset solution to a SDE), or solving an optimal portfolio management problem, amounts to solve a parabolic second-order PDE, that is a PDE of the form

$$\begin{aligned} \frac{\partial u}{\partial t}(t, x) + L_t u(t, x) \\ = f(t, x, u(t, x), \nabla u(t, x)), \quad (t, x) \in \mathbb{R}_+ \times \mathbb{R}^d \end{aligned} \quad (38)$$

where $\nabla u(t, x)$ is the gradient of $u(t, x)$ with respect to x and the linear differential operators L_t has the form equation (28).

The goal of this section is to explain the links between these PDEs and the original diffusion process, or some intermediate Markov process. We will distinguish between *linear* parabolic PDEs, where the function $f(t, x, y, z)$ does not depend on z and is linear in y , *semilinear* parabolic PDEs, where the function $f(t, x, y, z)$ does not depend on z but is nonlinear in y , and *quasi-linear* parabolic PDEs, where the function $f(t, x, y, z)$ is nonlinear in (y, z) . We will also discuss the links between diffusion processes and some *fully nonlinear* PDEs (Hamilton–Jacobi–Bellman (HJB) equations or variational inequalities) of the form

$$\begin{aligned} F\left(t, \frac{\partial u}{\partial t}(t, x), u(t, x), \nabla u(t, x), Hu(t, x)\right) = 0, \\ (t, x) \in \mathbb{R}_+ \times \mathbb{R}^d \end{aligned} \quad (39)$$

for some nonlinear function F , where Hu denotes the Hessian matrix of u with respect to the space variable x .

Such problems involve several notions of solutions discussed in the literature (*see viscosity solution*). In the sections “Brownian Motion, Ornstein–Uhlenbeck Process, and the Heat Equation” and “Linear Case”, we consider *classical solutions*, that is, solutions that are continuously differentiable with respect to the time variable, and twice continuously differentiable with respect to the space variables. In the sections “Quasi- and Semilinear PDEs and BSDEs” and

“Optimal Control, Hamilton–Jacobi–Bellman Equations, and Variational Inequalities”, because of the nonlinearity of the problem, classical solutions may not exist, and one must consider the weaker notion of viscosity solutions.

In the section “Brownian Motion, Ornstein–Uhlenbeck Process, and the Heat Equation”, we consider heat-like equations where the solution can be explicitly computed. The section “Linear Case” deals with linear PDEs, the section “Quasi- and Semilinear PDEs and BSDEs” deals with quasi- and semilinear PDEs and their links with BSDEs, and the section “Optimal Control, Hamilton–Jacobi–Bellman Equations, and Variational Inequalities” deals with optimal control problems.

Brownian Motion, Ornstein–Uhlenbeck Process, and the Heat Equation

The *heat equation* is the first example of a parabolic PDE with basic probabilistic interpretation (for which there is no need of stochastic calculus).

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) = \frac{1}{2} \Delta u(t, x), & (t, x) \in (0, +\infty) \times \mathbb{R}^d \\ u(0, x) = f(x), & x \in \mathbb{R}^d \end{cases} \quad (40)$$

where Δ denotes the Laplacian operator of $\mathbb{R}^d$. When f is a bounded measurable function, it is well known that the solution of this problem is given by the formula

$$u(t, x) = \int_{\mathbb{R}^d} f(y) g(x; t, y) dy \quad (41)$$

where

$$g(x; t, y) = \frac{1}{(2\pi t)^{d/2}} \exp\left(-\frac{|x - y|^2}{2t}\right) \quad (42)$$

$|\cdot|$ denotes the Euclidean norm on $\mathbb{R}^d$. g is often called the *fundamental solution* of the heat equation. We recognize that $g(x; t, y) dy$ is the law of $x + B_t$ where B is a standard d -dimensional Brownian motion. Therefore, equation (41) may be rewritten as

$$u(t, x) = \mathbb{E}[f(x + B_t)] \quad (43)$$

which provides a simple probabilistic interpretation of the solution of the heat equation in $\mathbb{R}^d$ as a particular case of equation (18). Note that equation (40)

involves the infinitesimal generator of the Brownian motion $(1/2)\Delta$.

Let us mention two other cases where the link between PDEs and stochastic processes can be done without stochastic calculus. The first one is the Black–Sholes model, solution to the SDE

$$dS_t = S_t(\mu dt + \sigma dB_t) \quad (44)$$

When $d = 1$, its infinitesimal generator is $Lf(x) = \mu xf'(x) + (\sigma^2/2)x^2 f''(x)$ and its law at time t when $S_0 = x$ is $l(x; t, y)$ dy where

$$l(x; t, y) = \frac{1}{\sigma y \sqrt{2\pi t}} \times \exp \left[-\frac{1}{2\sigma^2 t} \left(\log \frac{y}{x} - \left(\mu - \frac{\sigma^2}{2} \right) t \right)^2 \right] \quad (45)$$

Then, for any bounded and measurable f , elementary computations show that

$$u(t, x) = \int_0^\infty f(y) l(x; t, y) dy \quad (46)$$

satisfies

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) = Lu(t, x), & (t, x) \in (0, +\infty)^2 \\ u(0, x) = f(x), & x \in (0, +\infty) \end{cases} \quad (47)$$

Here again, this formula gives immediately the probabilistic interpretation

$$u(t, x) = \mathbb{E}[f(S_t) \mid S_0 = x] \quad (48)$$

The last example is the **Ornstein–Uhlenbeck** process in $\mathbb{R}$

$$dX_t = \beta X_t dt + \sigma dB_t \quad (49)$$

with $\beta \in \mathbb{R}$, $\sigma > 0$ and $X_0 = x$. The infinitesimal generator of this process is $Af(x) = \beta xf'(x) + (\sigma^2/2)f''(x)$. It can be easily checked that X_t is a Gaussian random variable with mean $x \exp(\beta t)$ and variance $\sigma^2(\exp(2\beta t) - 1)/2\beta$ with the convention that $(\exp(2\beta t) - 1)/2\beta = t$ if $\beta = 0$. Therefore, its probability density function is given by

$$h(x; t, y) = \sqrt{\frac{\beta}{\sigma^2 \pi (\exp(2\beta t) - 1)}}$$

$$\times \exp \left[-\frac{2\beta(y - x \exp(\beta t))^2}{\sigma^2(\exp(2\beta t) - 1)} \right] \quad (50)$$

Then, for any bounded and measurable f ,

$$u(t, x) = \int_{\mathbb{R}} f(y) h(x; t, y) dy = \mathbb{E}[f(X_t) \mid X_0 = x] \quad (51)$$

is solution of

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) = Au(t, x), & (t, x) \in (0, +\infty) \times \mathbb{R} \\ u(0, x) = f(x), & x \in \mathbb{R} \end{cases} \quad (52)$$

Linear Case

The probabilistic interpretations of the previous PDEs can be generalized to a large class of linear parabolic PDEs with arbitrary second-order differential operator, interpreted as the infinitesimal generator of a Markov process. Assume that the vector $b(t, x) \in \mathbb{R}^d$ and the $d \times r$ matrix $\sigma(t, x)$ are uniformly bounded and locally Lipschitz functions on $[0, T] \times \mathbb{R}^d$ and consider the SDE in $\mathbb{R}^d$

$$dX_t = b(t, X_t) dt + \sigma(t, X_t) dB_t \quad (53)$$

where B is a standard r -dimensional Brownian motion. Set $a = \sigma\sigma'$ and assume also that the $d \times d$ matrix $a(t, x)$ is uniformly Hölder and satisfies the uniform ellipticity condition: there exists $\gamma > 0$ such that for all $(t, x) \in [0, T] \times \mathbb{R}^d$ and $\xi \in \mathbb{R}^d$,

$$\sum_{i,j=1}^d a_{ij}(t, x) \xi_i \xi_j \geq \gamma |\xi|^2 \quad (54)$$

Let $(L_t)_{t \geq 0}$ be the family of time-inhomogeneous infinitesimal generators of the Feller diffusion X_t solution to the SDE (53), given by equation (28). Consider the Cauchy problem

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) + L_t u(t, x) + c(t, x)u(t, x) = f(t, x), & (t, x) \in [0, T] \times \mathbb{R}^d \\ u(T, x) = g(x), & x \in \mathbb{R}^d \end{cases} \quad (55)$$

where $c(t, x)$ is uniformly bounded and locally Hölder on $[0, T] \times \mathbb{R}^d$, $f(t, x)$ is locally Hölder on $[0, T] \times \mathbb{R}^d$, $g(x)$ is continuous on $\mathbb{R}^d$ and

$$\begin{aligned} |f(t, x)| + |g(x)| &\leq A \exp(a|x|), \\ \forall (t, x) \in [0, T] \times \mathbb{R}^d \end{aligned} \quad (56)$$

for some constants $A, a > 0$. Under these conditions, it follows easily from Theorems 6.4.5 and 6.4.6 of [10] that equation (55) admits a unique classical solution u such that

$$|u(t, x)| \leq A' \exp(a|x|) \quad \forall (t, x) \in [0, T] \times \mathbb{R}^d \quad (57)$$

for some constant $A' > 0$.

The following result is known as *Feynman–Kac formula* and can be deduced from equation (57) using exactly the same method as for [10, Th.6.5.3] and using the fact that, under our assumptions, X_t has finite exponential moments [10, Th.6.4.5].

Theorem 4 *Under the previous assumptions, the solution of the Cauchy problem (55) is given by*

$$\begin{aligned} u(t, x) &= \mathbb{E} \left[g(X_T) \exp \left(\int_t^T c(s, X_s) ds \right) \mid X_t = x \right] \\ &\quad - \mathbb{E} \left[\int_t^T f(s, X_s) \right. \\ &\quad \times \exp \left(\int_t^s c(\alpha, X_\alpha) d\alpha \right) ds \mid X_t = x \Big] \end{aligned} \quad (58)$$

Let us mention that this result can be extended to parabolic linear PDEs on bounded domains [10, Th.6.5.2] and to elliptic linear PDEs on bounded domains [10, Th.6.5.1].

Example 5 European Options The Feynman–Kac formula has many applications in finance. Let us consider the case of an European option on a one-dimensional Markov asset $(S_t, t \geq 0)$ with payoff

$g(S_u, 0 \leq u \leq T)$. The free arbitrage value at time t of this option is

$$V_t = \mathbb{E}[e^{-r(T-t)} g(S_u, t \leq u \leq T) \mid \mathcal{F}_t] \quad (59)$$

By the Markov property (1), this quantity only depends on S_t and t [10, Th.2.1.2]. The Feynman–Kac formula (58) allows one to characterize V in the case where g depends only on S_T and S is a Feller diffusion.

Most often, the asset SDE

$$dS_t = S_t(\mu(t, S_t) dt + \sigma(t, S_t) dB_t) \quad (60)$$

cannot satisfy the uniform ellipticity assumption (54) in the neighborhood of 0. Therefore, Theorem 4 does not apply directly. This is a general difficulty for financial models. However, in most cases (and in all the examples below), it can be overcome by taking the logarithm of the asset price. In our case, we assume that the process $(\log S_t, 0 \leq t \leq T)$ is a Feller diffusion on $\mathbb{R}$ with time-inhomogeneous generator

$$L_t \phi(y) = \frac{1}{2} a(t, y) \phi''(y) + b(t, y) \phi'(y) \quad (61)$$

that satisfy the assumptions of Theorem 4. This holds for example for the Black–Scholes model (32). This assumption implies that S is a Feller diffusion on $(0, +\infty)$ whose generator takes the form

$$\tilde{L}_t \phi(x) = \frac{1}{2} \tilde{a}(t, x) x^2 \phi''(x) + \tilde{b}(t, x) x \phi'(x) \quad (62)$$

where $\tilde{a}(t, x) = a(t, \log x)$ and $\tilde{b}(t, x) = b(t, \log x) + a(t, \log x)/2$.

Assume also that $g(x)$ is continuous on $\mathbb{R}_+$ with polynomial growth when $x \rightarrow +\infty$. Then, by Theorem 4, the function

$$v(t, y) = \mathbb{E}[e^{-r(T-t)} g(S_T) \mid \log S_t = y] \quad (63)$$

is solution to the Cauchy problem

$$\begin{cases} \frac{\partial v}{\partial t}(t, y) + L_t v(t, y) \\ -rv(t, y) = 0, & (t, y) \in [0, T] \times \mathbb{R} \\ v(T, y) = g(\exp(y)), & y \in \mathbb{R} \end{cases} \quad (64)$$

Making the change of variable $x = \exp(y)$, $u(t, x) = v(t, \log x)$ is solution to

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) + \tilde{b}(t, x)x \frac{\partial u}{\partial x}(t, x) + \frac{1}{2}\tilde{a}(t, x)x^2 \frac{\partial^2 u}{\partial x^2}(t, x) - rv(t, x) = 0, & (t, x) \in [0, T) \times (0, +\infty) \\ u(T, x) = g(x), & x \in (0, +\infty) \end{cases} \quad (65)$$

and $V_t = u(t, S_t)$. The Black–Scholes PDE (37) is a particular case of this result.

Example 6 An Asian Option We give an example of a path-dependent option for which the uniform ellipticity condition of the matrix a does not hold. An Asian option is an option where the payoff is determined by the average of the underlying price over the period considered. Consider the Asian call option

$$\left(\frac{1}{T} \int_0^T S_u du - K \right)^+ \quad (66)$$

on a Black–Scholes asset $(S_t, t \geq 0)$ following

$$dS_t = rS_t dt + \sigma S_t dB_t \quad (67)$$

$$\begin{cases} \frac{\partial u}{\partial t} + \frac{\sigma^2}{2}x^2 \frac{\partial^2 u}{\partial x^2} + rx \frac{\partial u}{\partial x} + \frac{1}{T}x \frac{\partial u}{\partial y} - ru = 0, & (t, x, y) \in [0, T) \times (0, +\infty) \times \mathbb{R} \\ u(T, x, y) = (y/T - K)^+, & (x, y) \in (0, +\infty) \times \mathbb{R} \end{cases} \quad (72)$$

where B is a standard one-dimensional Brownian motion. The free arbitrage price at time t is

$$\mathbb{E} \left[e^{-r(T-t)} \left(\frac{1}{T} \int_0^T S_u du - K \right)^+ \middle| S_t \right] \quad (68)$$

To apply the Feynman–Kac formula, one must express this quantity as the (conditional) expectation

$$\begin{cases} \frac{\partial \varphi}{\partial t}(t, z) + \frac{\sigma^2}{2}z^2 \frac{\partial^2 \varphi}{\partial z^2}(t, z) - \left(\frac{1}{T} + rz \right) \frac{\partial \varphi}{\partial z}(t, z) + r\varphi(t, z) = 0, & (t, z) \in [0, T) \times \mathbb{R} \\ \varphi(T, z) = -(z)^+/T, & z \in \mathbb{R} \end{cases} \quad (74)$$

of the value at time T of some Markov quantity. This can be done by introducing the process

$$A_t = \int_0^t S_u du, \quad 0 \leq t \leq T \quad (69)$$

It is straightforward to check that (S, A) is a Feller diffusion on $(0, +\infty)^2$ with infinitesimal generator

$$\begin{aligned} Lf(x, y) &= rx \frac{\partial f}{\partial x}(x, y) + \frac{\sigma^2}{2}x^2 \frac{\partial^2 f}{\partial x^2}(x, y) \\ &\quad + \frac{1}{T}x \frac{\partial f}{\partial y}(x, y) \end{aligned} \quad (70)$$

Although considering the change of variable $(\log S, A)$, Theorem 4 does not apply to this process because the infinitesimal generator is degenerated (without second-order derivative in y). Formally, the Feynman–Kac formula would give that

$$\begin{aligned} u(t, x, y) &:= \mathbb{E}[e^{-r(T-t)}(A_T/T - K)^+ \mid S_t = x, A_t = y] \\ &\quad (71) \end{aligned}$$

is solution to the PDE

Actually, it is possible to justify the previous statement in the specific case of a one-dimensional Black–Scholes asset: u can be written as

$$u(t, x, y) = e^{-r(T-t)} x \varphi \left(t, \frac{KT - y}{x} \right) \quad (73)$$

(see [20]) where $\varphi(t, z)$ is the solution of the one-dimensional parabolic PDE

From this, it is easy to check that u solves equation (72).

Note that this relies heavily on the fact that the underlying asset follows the Black–Scholes model. As far as we know, no rigorous justification of

Feynman–Kac formula is available for Asian options on more general assets.

Quasi- and Semilinear PDEs and BSDEs

The link between quasi- and semilinear PDEs and BSDEs is motivated by the following formal argument. Consider the semilinear PDE

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) + L_t u(t, x) = f(u(t, x)) \\ (t, x) \in (0, T) \times \mathbb{R} \\ u(T, x) = g(x) \quad x \in \mathbb{R} \end{cases} \quad (75)$$

where (L_t) is the family of infinitesimal generators of a time-inhomogeneous Feller diffusion $(X_t, t \geq 0)$. Assume that this PDE admits a classical solution $u(t, x)$. Assume also that we can find a unique adapted process $(Y_t, 0 \leq t \leq T)$ such that

$$Y_t = \mathbb{E}[g(X_T) - \int_t^T f(Y_s) ds \mid \mathcal{F}_t] \quad \forall t \in [0, T] \quad (76)$$

Now, by Itô's formula applied to $u(t, X_t)$,

$$u(t, X_t) = \mathbb{E}[g(X_T) - \int_t^T f(u(s, X_s)) ds \mid \mathcal{F}_t] \quad (77)$$

Therefore, $Y_t = u(t, X_t)$ and the stochastic process Y provides a probabilistic interpretation of the solution of the PDE (75). Now, by the martingale decomposition theorem, if Y satisfies (76), there exists an adapted process $(Z_t, 0 \leq t \leq T)$ such that

$$Y_t = g(X_T) - \int_t^T f(Y_s) ds - \int_t^T Z_s dB_s \quad \forall t \in [0, T] \quad (78)$$

solution of the SDE $dY_t = f(Y_t) dt + Z_t dB_t$ with terminal condition $Y_T = g(X_T)$.

The following definition of a BSDE generalizes the previous situation. Given functions $b_i(t, x)$ and $\sigma_{ij}(t, x)$ that are globally Lipschitz in x and locally bounded ($1 \leq i, j \leq d$) and a standard d -dimensional Brownian motion B , consider the unique solution X of the time-inhomogeneous SDE

$$dX_t = b(t, X_t) dt + \sigma(t, X_t) dB_t \quad (79)$$

with initial condition $X_0 = x$. Consider also two functions $f : [0, T] \times \mathbb{R}^d \times \mathbb{R}^k \times \mathbb{R}^{k \times d} \rightarrow \mathbb{R}^k$ and $g : \mathbb{R}^d \rightarrow \mathbb{R}^k$. We say that $((Y_t, Z_t), t \geq 0)$ solve the BSDE

$$dY_t = f(t, X_t, Y_t, Z_t) dt + Z_t dB_t \quad (80)$$

with terminal condition $g(X_T)$ if Y and Z are progressively measurable processes with respect to the Brownian filtration $\mathcal{F}_t = \sigma(B_s, s \leq t)$ such that, for any $0 \leq t \leq T$,

$$Y_t = g(X_T) - \int_t^T f(s, X_s, Y_s, Z_s) ds - \int_t^T Z_s dB_s \quad (81)$$

Example 4 corresponds to $g(x) = (x - K)^+$, $f(t, x, y, z) = -ry + z(\mu - r)/\sigma$ and $Z_t = \sigma \pi_t$. Note that the role of the implicit unknown process Z is to make Y adapted.

The existence and uniqueness of (Y, Z) solving equation (81) hold under the assumptions that $g(x)$ is continuous with polynomial growth in x , $f(t, x, y, z)$ is continuous with polynomial growth in x and linear growth in y and z , and f is uniformly Lipschitz in y and z . Let us denote by (A) all these assumptions. We refer to [17] for the proof of this result and the general theory of BSDEs (*see also forward-backward SDEs*).

Consider the quasi-linear parabolic PDE

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) + L_t u(t, x) = f(t, x, u(t, x), \nabla_x u(t, x) \sigma(t, x)), & (t, x) \in (0, T) \times \mathbb{R}^d \\ u(T, x) = g(x), & x \in \mathbb{R}^d \end{cases} \quad (82)$$

where B is the same Brownian motion as the one driving the Feller diffusion X . In other words, Y is

The following results give the links between the BSDE (80) and the PDE (82).

Theorem 5 ([15], Th.4.1). Assume that $b(t, x)$, $\sigma(t, x)$, $f(t, x, y, z)$, and $g(x)$ are continuous and differentiable with respect to the space variables x, y, z with uniformly bounded derivatives. Assume also that b, σ , and f are uniformly bounded and that $a = \sigma \sigma'$ is uniformly elliptic. Then equation (82) admits a unique classical solution u and

$$Y_t = u(t, X_t) \quad \text{and} \quad Z_t = \nabla_x u(t, X_t) \sigma(t, X_t) \quad (83)$$

Theorem 6 ([17], Th.2.4). Assume (A) and that $b(t, x)$ and $\sigma(t, x)$ are globally Lipschitz in x and locally bounded. Define the function $u(t, x) = Y_t^{t,x}$, where $Y^{t,x}$ is the solution to the BSDE (82) on the time interval $[t, T]$, where X is solution to the SDE (79) with initial condition $X_t = x$. Then u is a viscosity solution of equation (82).

Theorem 5 gives an interpretation of the solution of a BSDE in terms of the solution of a quasi-linear PDE. In particular, in Example 4, it gives the usual interpretation of the hedging strategy $\pi_t = Z_t/\sigma$ as the Δ -hedge of the option price. Note also that Theorem 5 implies that the process (X, Y, Z) is Markov—a fact which is not obvious from the definition. Conversely, Theorem 6 shows how to construct a viscosity solution of a quasi-linear PDE from BSDEs.

BSDEs provide an indirect tool to compute quantities related to a solution X of the SDE (such as the hedging price and strategy of an option based on the process X). BSDEs also have links with general stochastic control problems, that we will not mention (see **BSDEs**). Here, we give an example of application to the pricing of an American put option.

Example 7 Pricing of an American Put Option Consider a Black–Scholes underlying asset S and assume for simplicity that the risk-free interest rate r is zero. The price of an **American put option** on S with strike K and maximal exercise policy T is given by

$$\sup_{0 \leq \tau \leq T} \mathbb{E}^*[(K - S_\tau)^+] \quad (84)$$

where τ is a stopping time and where $\mathbb{P}^*$ is the risk-neutral probability measure, under which the process S is simply a Black–Scholes asset with zero drift.

In the case of an European put option, the price is given by the solution of the BSDE

$$Y_t = (K - S_T)^+ - \int_t^T Z_s dB_s \quad (85)$$

by a similar argument as in Example 4. In the case of an American put option, the price at time t is necessarily bigger than $(K - S_t)^+$. It is therefore natural to include this condition by considering the BSDE (85) reflected on the obstacle $(K - S_t)^+$. Mathematically, this corresponds to the problem of finding adapted processes Y, Z , and R such that

$$\begin{cases} Y_t = (K - S_T)^+ - \int_t^T Z_s dB_s + R_T - R_t \\ Y_t \geq (K - S_t)^+ \\ R \text{ is continuous, increasing, } R_0 = 0 \text{ and} \\ \int_0^T [Y_t - (K - S_t)^+] dR_t = 0 \end{cases} \quad (86)$$

The process R increases only when $Y_t = (K - S_t)^+$ in such a way that Y cannot cross this obstacle. The existence of a solution of this problem is a particular case of general results, (see [7]). As a consequence of the following theorem, this reflected BSDE gives a way to compute the price of the American put option.

Theorem 7 ([7], Th.7.2). The American put option has the price Y_0 , where (Y, Z, R) solves the reflected BSDE (86).

The essential argument of the proof is the following. Fix $t \in [0, T)$ and a stopping time $\tau \in [t, T]$. Since

$$Y_\tau - Y_t = R_t - R_\tau + \int_t^\tau Z_s dB_s \quad (87)$$

and because R is increasing, $Y_t = \mathbb{E}^*[Y_\tau + R_\tau - R_t | \mathcal{F}_t] \geq \mathbb{E}^*[(K - S_\tau)^+ | \mathcal{F}_t]$. Conversely, if $\tau_t^* = \inf\{u \in [t, T] : Y_u = (K - S_u)^+\}$, because $Y > (K - S)^+$ on $[t, \tau_t^*)$, R is constant on this interval and

$$Y_t = \mathbb{E}^*[Y_{\tau_t^*} + R_{\tau_t^*} - R_t | \mathcal{F}_t] = \mathbb{E}^*[(K - S_{\tau_t^*})^+] \quad (88)$$

Therefore,

$$Y_t = \text{ess sup}_{t \leq \tau \leq T} \mathbb{E}^*[(K - S_\tau)^+ | \mathcal{F}_t] \quad (89)$$

which gives another interpretation for the solution Y of the reflected BSDE. Applying this for $t = 0$ yields $Y_0 = \sup_{\tau \leq T} \mathbb{E}^*[(K - S_\tau)^+]$ as stated.

Moreover, as shown by the previous computation, the process Y provides an interpretation of the optimal exercise policy as the first time where Y hits the obstacle $(K - S)^+$. This fact is actually natural from equation (89); the optimal exercise policy is the first time where the current payoff equals the maximal future expected payoff.

As it will appear in the next section, as the solution of an optimal stopping problem, if $S_0 = x$, the price of this American put option is $u(0, x)$, where u is the solution of the nonlinear PDE

$$\begin{cases} \min \left\{ u(t, x) - (K - x)^+; -\frac{\partial u}{\partial t}(t, x) - \frac{\sigma^2}{2} x^2 \frac{\partial^2 u}{\partial x^2}(t, x) \right\} = 0, & (t, x) \in (0, T) \times (0, +\infty) \\ u(T, x) = (K - x)^+, & x \in (0, +\infty) \end{cases} \quad (90)$$

Therefore, similarly as in Theorem 6, the reflected BSDE (84) provides a probabilistic interpretation of the solution of this PDE.

The (formal) essential argument of the proof of this result can be summarized as follows (for details, see [14, Section V.3.1]). Consider the solution u of equation (90) and apply Itô's formula to $u(t, S_t)$. Then, for any stopping time $\tau \in [0, T]$,

$$\begin{aligned} u(0, x) &= \mathbb{E}[u(\tau, S_\tau)] - \mathbb{E} \left[\int_0^\tau \left(\frac{\partial u}{\partial t}(t, S_t) \right. \right. \\ &\quad \left. \left. + \frac{\sigma^2}{2} S_t^2 \frac{\partial^2 u}{\partial x^2}(t, S_t) \right) ds \right] \end{aligned} \quad (91)$$

Because u is solution of equation (90), $u(0, x) \geq \mathbb{E}[u(\tau, S_\tau)] \geq \mathbb{E}[(K - S_\tau)^+]$. Hence, $u(0, x) \geq \sup_{0 \leq \tau \leq T} \mathbb{E}[(K - S_\tau)^+]$.

Conversely, if $\tau^* = \inf\{0 \leq t \leq T : u(t, S_t) = (K - S_t)^+\}$, then

$$\frac{\partial u}{\partial t}(t, S_t) + \frac{\sigma^2}{2} S_t^2 \frac{\partial^2 u}{\partial x^2}(t, S_t) = 0 \quad \forall t \in [0, \tau^*] \quad (92)$$

Therefore, for $\tau = \tau^*$, all the inequalities in the previous computation are equalities and $u(0, x) = \sup_{0 \leq \tau \leq T} \mathbb{E}[(K - S_\tau)^+]$.

Optimal Control, Hamilton–Jacobi–Bellman Equations, and Variational Inequalities

We discuss only two main families of **stochastic control problems**: finite horizon and the optimal stopping problems. Other classes of optimal problems appearing in finance are mentioned in the end of this section.

Finite Horizon Problems

The study of optimal control problems with finite horizon is motivated, for example, by the ques-

tions of portfolio management, quadratic hedging of options, or **super-hedging** cost for **uncertain volatility models**.

Let us consider a controlled diffusion X^α in $\mathbb{R}^d$ solution to the SDE

$$dX_t^\alpha = b(X_t^\alpha, \alpha_t) dt + \sigma(X_t^\alpha) dB_t \quad (93)$$

where B is a standard r -dimensional Brownian motion and the control α is a given progressively measurable process taking values in some compact metric space A . Such a control is called *admissible*. For simplicity, we consider the time-homogeneous case and we assume that the control does not act on the diffusion coefficient σ of the SDE. Assume that $b(x, a)$ is bounded, continuous, and Lipschitz in the variable x , uniformly in $a \in A$. Assume also that σ is Lipschitz and bounded. For any $a \in A$, we introduce the linear differential operator

$$\begin{aligned} L^a \varphi &= \frac{1}{2} \sum_{i,j=1}^d \left(\sum_{k=1}^d \sigma_{ik}(x) \sigma_{jk}(x) \right) \frac{\partial^2 \varphi}{\partial x_i \partial x_j} \\ &\quad + \sum_{i=1}^d b_i(x, a) \frac{\partial \varphi}{\partial x_i} \end{aligned} \quad (94)$$

which is the infinitesimal generator of X^α when α is a constant equal to $a \in A$.

A typical form of finite horizon optimal control problems in finance consists in computing

$$u(t, x) = \inf_{\alpha \text{ admissible}} \mathbb{E} \left[e^{-rT} g(X_T^\alpha) + \int_t^T e^{-rt} f(X_t^\alpha, \alpha_t) dt \mid X_t^\alpha = x \right] \quad (95)$$

where f and g are continuous and bounded functions and to find an optimal control α^* that realizes the minimum. Moreover, it is desirable to find a *Markov* optimal control, that is, an optimal control having the form $\alpha_t^* = \psi(t, X_t)$. Indeed, in this case, the controlled diffusion X^{α^*} is a Markov process.

In the case of nondegenerate diffusion coefficient, we have the following link between the optimal control problems and a semilinear PDEs.

Theorem 8 *Under the additional assumption that σ is uniformly elliptic, u is the unique bounded classical solution of the Hamilton–Jacobi–Bellman (HJB) equation*

$$\begin{cases} \frac{\partial u}{\partial t}(t, x) + \inf_{a \in A} \{L^a u(t, x) + f(x, a)\} - ru(t, x) = 0, & (t, x) \in (0, T) \times \mathbb{R}^d \\ u(T, x) = g(x), & x \in \mathbb{R}^d \end{cases} \quad (96)$$

Furthermore, a Markov control $\alpha_t^* = \psi(t, X_t)$ is optimal for a fixed initial condition x and initial time $t = 0$ if and only if

$$\begin{aligned} L^{\psi(t, x)} u(t, x) + f(x, \psi(t, x)) \\ = \inf_{a \in A} \{L^a u(t, x) + f(x, a)\} \end{aligned} \quad (97)$$

for almost every $(t, x) \in [0, T] \times \mathbb{R}^d$.

This is Theorem III.2.3 of [3] restricted to the case of precise controls (see later).

Here again, the essential argument of the proof can be easily (at least formally) written: consider any admissible control α and the corresponding controlled diffusion X^α with initial condition $X_0 = x$. By Itô's formula applied to $e^{-rt} v(t, X_t^\alpha)$, where v is the solution of equation (96),

$$\mathbb{E}[e^{-rT} v(T, X_T^\alpha)] = v(0, x) + \int_0^T e^{-rt} \left[\frac{\partial v}{\partial t}(t, X_t^\alpha) + L^{\alpha_t} v(t, X_t^\alpha) + r v(t, X_t^\alpha) \right] ds$$

$$\times \mathbb{E} \left[\frac{\partial v}{\partial t}(t, X_t^\alpha) + L^{\alpha_t} v(t, X_t^\alpha) + r v(t, X_t^\alpha) \right] ds \quad (98)$$

Therefore, by equation (96),

$$\begin{aligned} v(0, x) \\ \leq \mathbb{E} \left[e^{-rT} g(X_T^\alpha) + \int_0^T e^{-rt} f(X_t^\alpha, \alpha_t) dt \mid X_0^\alpha = x \right] \end{aligned} \quad (99)$$

for any admissible control α . Now, for the Markov control α^* defined in Theorem 8, all the inequalities in the previous computation are equalities. Hence $v = u$.

The cases where σ is not uniformly elliptic or where σ is also dependent on the current control α_t are much more difficult. In both cases, it is necessary to enlarge the set of admissible control by considering *relaxed controls*, that is, controls that belong to the set $\mathcal{P}(A)$ of probability measures on A . For such a control α , the terms $b(x, \alpha_t)$ and

$f(x, \alpha_t)$ in equations (93) and (95) are replaced by $\int b(x, a) \alpha_t(da)$ and $\int f(x, a) \alpha_t(da)$, respectively. The admissible controls of the original problem correspond to relaxed controls that are Dirac masses at each time. These are called *precise controls*.

The value $\tilde{u}$ of this new problem is defined as in equation (95), but the infimum is taken over all progressively measurable processes α taking values in $\mathcal{P}(A)$. It is possible to prove under general assumptions that both problems give the same value: $\tilde{u} = u$ (cf. [3, Cor.I.2.1] or [8, Th.2.3]).

In these cases, one usually cannot prove the existence of a classical solution of equation (96). The weaker notion of **viscosity solution** is generally the correct one. In all the cases treated in the literature, $u = \tilde{u}$ solves the same HJB equation as in Theorem 8, except that the infimum is taken over $\mathcal{P}(A)$ instead of A (cf. [3, Th.IV.2.2] for the case without control on σ). However, it is not trivial at all in general to obtain a result on precise controls from the result on relaxed controls. This is due to the fact that

usually no result is available on the existence and the characterization of a Markov-relaxed optimal control. The only examples where it has been done require restrictive assumptions (cf. [8, Cor.6.8]). However, in most of the financial applications, the value function u is the most useful information. In practice, one usually only needs to compute a control that give an expected value arbitrarily close to the optimal one.

Optimal Stopping Problems

Optimal stopping problems arise in finance, for example, for the **American options** pricing (when

$$\begin{cases} \max \left\{ u(t, x) - g(t, x); -\frac{\partial u}{\partial t}(t, x) - L_t u(t, x) + ru(t, x) - f(t, x) \right\} = 0, & (t, x) \in (0, T) \times \mathbb{R}^d \\ u(T, x) = g(T, x) & x \in \mathbb{R}^d \end{cases} \quad (103)$$

to sell a claim, an asset?) or in production models (when to extract or product a good? when to stop production?).

Let us consider a Feller diffusion X in $\mathbb{R}^d$ solution to the SDE

$$dX_t = b(t, X_t) dt + \sigma(t, X_t) dB_t \quad (100)$$

where B is a standard d -dimensional Brownian motion. As in equation (28), let $(L_t)_{t \geq 0}$ denote its family of time-inhomogeneous infinitesimal generators. Denote by $\Pi(t, T)$ the set of stopping times valued in $[t, T]$.

A typical form of optimal stopping problems consists in computing

$$\begin{aligned} u(t, x) = & \inf_{\tau \in \Pi(t, T)} \mathbb{E} \left[e^{-r(\tau-t)} g(\tau, X_\tau) \right. \\ & \left. + \int_t^\tau e^{-r(s-t)} f(s, X_s) ds \mid X_t = x \right] \end{aligned} \quad (101)$$

and to characterize an optimal stopping time.

Assume that $b(t, x)$ is bounded and continuously differentiable with bounded derivatives and that $\sigma(t, x)$ is bounded, continuously differentiable with respect to t and twice continuously differentiable with respect to x with bounded derivatives. Assume also that σ is uniformly elliptic. Finally,

assume that $g(t, x)$ is differentiable with respect to t and twice differentiable with respect to x and that

$$|f(t, x)| + \left| \frac{\partial g}{\partial t}(t, x) \right| + \sum_{i=1}^d \left| \frac{\partial g}{\partial x_i}(t, x) \right| \leq C e^{\mu|x|} \quad (102)$$

for positive constants C and μ .

Theorem 9 ([2], Sec.III.4.9). *Under the previous assumptions, $u(t, x)$ admits first-order derivatives with respect to t and second-order derivatives with respect to x that are L^p for all $1 \leq p < \infty$. Moreover, u is the solution of the variational inequality*

The proof of this result is based on a similar (formal) justification as the one we gave for equation (90). We refer to [12] for a similar result under weaker assumptions more suited to financial models when $f = 0$ (this is in particular the case for American options).

In some cases (typically with $f = 0$, see [11]), it can be shown that the infimum in equation (101) is attained for the stopping time

$$\tau^* = \inf \{ t \leq s \leq T : u(s, X_s^{t,x}) = g(s, X_s^{t,x}) \} \quad (104)$$

where $X^{t,x}$ is the solution of the SDE (100) with initial condition $X_t^{t,x} = x$.

Generalizations and Extensions

An optimal control problem can also be solved through the optimization of a family of BSDEs related to the laws of the controlled diffusions. On this question, we refer to [19] and **BSDEs**.

In this section, we considered only very specific optimal control problems. Other important families of optimal control problems are given by impulse control problems, where the control may induce a jump of the underlying stochastic process, or ergodic control problems, where the goal is to optimize a quantity related to the stationary behavior of the controlled

diffusion. Impulse control has applications, for example, in stock or resource management problems. In the finite horizon case, when the underlying asset follows a model with stochastic or elastic volatility or when the market is incomplete, other optimal control problems can be considered, such as characterizing the superhedging cost, or minimizing some risk measure. Various constraints can be included in the optimal control problem, such as maximizing the expectation of an utility with the constraint that this utility has a fixed volatility, or minimizing the volatility for a fixed expected utility. One can also impose Gamma constraints on the control. Another important extension of optimal control problems arises when one wants to solve numerically an HJB equation. Usual discretization methods require to restrict to a bounded domain and to fix artificial boundary conditions. The numerical solution can be interpreted as the solution of an optimal control problem in a bounded domain. In this situation, a crucial question is to quantify the impact on the discretized solution of an error on the artificial boundary condition (which usually cannot be computed exactly).

On Numerical Methods

The Feynman–Kac formula for linear PDEs allows one to use **Monte Carlo methods** to compute the solution of the PDE. They are especially useful when the solution of the PDE has to be computed at a small number of points, or when dimension is large (typically larger or equal to 4), since they provide a rate of convergence independent of the dimension.

Concerning quasi- or semilinear PDEs and some optimal control problems (e.g., American put options in the section “Quasi- and Semilinear PDEs and BSDEs”), interpretations in terms of BSDEs provide indirect Monte Carlo methods of numerical computation (see [1] for **Bermudan options** or [4, 6] for general BSDEs schemes). These methods have the advantage that they do not require to consider artificial boundary conditions. However, their speed of convergence to the exact solution is still largely unknown, and could depend on the dimension of the problem.

For high dimensional HJB equations, the analytical discretization methods lead to important numerical problems. First, these methods need to solve an optimization problem at each node of the discretization grid, which can be very costly in high dimension

or difficult depending on the particular constraints imposed on the control. Moreover, these methods require to localize the problem, that is, to solve the problem in a bounded domain with artificial boundary conditions, which are usually difficult to compute precisely. This localization problem can be solved by computing the artificial boundary condition with a Monte Carlo method based on BSDEs. However, the error analysis of this method is based on the probabilistic interpretation of HJB equations in bounded domains, which is a difficult problem in general.

End Notes

^aA Markov semigroup family $(P_t, t \geq 0)$ on $\mathbb{R}^d$ is a family of bounded linear operators of norm 1 on the set of bounded measurable functions on $\mathbb{R}^d$ equipped with the L^∞ norm, which satisfies equation (8).

^bThis is not the most general definition of Feller semigroups (see [21, Def.III.6.5]). In our context, because we only introduce analytical objects from stochastic processes, the semigroup (P_t) is naturally defined on the set of bounded measurable functions.

^cThe strong continuity of a semigroup is usually defined as $\|P_t f - f\| \rightarrow 0$ as $t \rightarrow 0$ for all $f \in C_0(\mathbb{R}^d)$. However, in the case of Feller semigroups, this is equivalent to the weaker formulation (10) (see [21, Lemma III.6.7]).

Doob–Meyer Decomposition

Submartingales are processes that grow on average. Subject to some condition of uniform integrability, they can be written uniquely as the sum of a martingale and a predictable increasing process. This result is known as the *Doob–Meyer decomposition*.

Consider a filtered probability space $(\Omega, \mathcal{F}, \mathbf{F}, P)$. It consists of a probability space $(\Omega, \mathcal{F}, P)$ and a *filtration* $\mathbf{F} = (\mathcal{F}_t)_{t \geq 0}$, that is, an increasing family of sub- σ -fields of $\mathcal{F}$. The σ -field $\mathcal{F}_t$ stands for the information available at time t . A random event A belongs to $\mathcal{F}_t$, if we know at time t , whether it will take place or not, that is, A does not depend on randomness in the future. For technical reasons, one typically assumes right continuity, that is, $\mathcal{F}_t = \bigcap_{s > t} \mathcal{F}_s$.

A *martingale* (see **Martingales**) (respectively *submartingale*, *supermartingale*) is an adapted, integrable process $(X_t)_{t \in \mathbb{R}_+}$ satisfying

$$E(X_t | \mathcal{F}_s) = X_s \quad (1)$$

(respectively $\geq X_s$, $\leq X_s$) for $s \leq t$. Moreover, we require these processes to be a.s. càdlàg, that is, right-continuous with left-hand limits. *Adaptedness* means that X_t is $\mathcal{F}_t$ -measurable, that is, the random value X_t is known at the latest at time t . *Integrability* $E(|X_t|) < \infty$ is needed for the conditional expectation to be defined. The crucial martingale equality (1) means that the best prediction of future values of X is the current value, that is, X will stay on the current level on average. In other words, it does not exhibit any positive or negative trend. If X denotes the price of a security, this asset does not produce profits or losses on average. Submartingales, on the other hand, grow on average. Put differently, they show an upward trend compared to a martingale. This loose statement is made precise in terms of the Doob–Meyer decomposition.

As a starting point, consider a discrete-time process $X = (X_t)_{t=0,1,2,\dots}$. In discrete time, a process X is called *predictable* if X_t is $\mathcal{F}_{t-1}$ -measurable for $t = 1, 2, \dots$. This means that the value X_t is known already one period ahead. The *Doob decomposition* states that any submartingale X can be written uniquely as

$$X_t = M_t + A_t \quad (2)$$

with a martingale M and an increasing predictable process A satisfying $A_0 = 0$. While the intuitive meaning of M and A may not be obvious, the corresponding decomposition of the increments $\Delta X_t := X_t - X_{t-1}$ is easier to understand.

$$\Delta X_t = \Delta M_t + \Delta A_t \quad (3)$$

can be interpreted in the sense that the increment ΔX_t consists of a predictable trend ΔA_t and a random deviation ΔM_t from that trend. Its implication $\Delta A_t = E(\Delta X_t | \mathcal{F}_{t-1})$ means that ΔA_t is the best prediction of ΔX_t in a mean-square sense and based on the information up to time $t - 1$.

The natural decomposition (3) does not make sense for continuous time processes but an analog of equation (2) still exists. To this end, the notion of predictability must be extended to continuous time. A process $X = (X_t)_{t \in \mathbb{R}_+}$ is called *predictable* if—viewed as a mapping on $\Omega \times \mathbb{R}_+$ —it is measurable with respect to the σ -field generated by all adapted, left-continuous processes. Intuitively, this rather abstract definition means that X_t is known slightly ahead of time t . In view of the discrete-time case, it may seem more natural to require that X_t be $\mathcal{F}_{t-}$ -measurable, where $\mathcal{F}_{t-}$ stands for the smallest sub- σ -field containing all $\mathcal{F}_s$, $s < t$. However, this slightly weaker condition turns out to be too weak for the general theory.

In order for a decomposition (2) into a martingale M and a predictable increasing process A to exist, one must assume some uniform integrability of X . The process X must belong to the so-called *class (D)*, which amounts to a rather technical condition implying $\sup_{t \geq 0} E(|X_t|) \leq \infty$ but being itself implied by $E(\sup_{t \geq 0} |\bar{X}_t|) \leq \infty$. For its precise definition, we need to introduce the concept of a stopping time, which is not only an indispensable tool for the general theory of stochastic processes but also interesting for applications, for example, in mathematical finance. A $[0, \infty]$ -valued random variable T is called *stopping time* if $\{T \leq t\} \in \mathcal{F}_t$ for any $t \geq 0$. Intuitively, T stands for a random time, which is generally not known in advance but at the latest once it has happened (e.g., the time of a phone call, the first time when a stock hits 100, the time when you crash your car into a tree). In financial applications, it appears, for example, as the exercise time of an American option.

Stopping times can be classified by their degree of suddenness. *Predictable* stopping times do not come

entirely as a surprise because one anticipates them. Formally, a stopping time T is called *predictable* if it allows for an *announcing sequence*, that is, for a sequence $(T_n)_{n \in \mathbb{N}}$ of stopping times satisfying $T_0 < T_1 < T_2 < \dots$ on $\{T > 0\}$ and $T_n \rightarrow T$ as $n \rightarrow \infty$. This is the case for a continuous stock price hitting 100 or for the car crashing into a tree, because you can literally see the level 100 or the tree coming increasingly closer. Phone calls, strikes of lightning, or jumps of Lévy process, on the other hand, are of an entirely different kind because they happen completely out of the blue. Such stopping times T are called *totally inaccessible*, which formally means that $P(S = T < \infty) = 0$ for all predictable stopping times S .

Coming back to our original theme, a process X is said to be of *class (D)* if the set $\{X_T : T \text{ finite stopping time}\}$ is uniformly integrable, which in turn means that

$$\lim_{c \rightarrow \infty} \sup_{T \text{ finite stopping time}} E(1_{\{|X_T| > c\}} |X_T|) = 0$$

The *Doob–Meyer decomposition* can now be stated as follows:

Theorem 1 *Any submartingale X of class (D) allows for a unique decomposition*

$$X_t = M_t + A_t \quad (4)$$

with a martingale M and some predictable increasing process A satisfying $A_0 = 0$.

The martingale M turns out to be of class (D) as well, which implies that it converges a.s. and in L^1 to some terminal random variable M_∞ . Since the whole martingale M can be recovered from its limit via $M_t = E(M_\infty | \mathcal{F}_t)$, one can formally identify such *uniformly integrable martingales* with their limit.

In the case of an Itô process

$$dX_t = H_t dW_t + K_t dt \quad (5)$$

the Doob–Meyer decomposition is easily obtained. Indeed, we have $M_t = X_0 + \int_0^t H_s dW_s$ and $A_t = \int_0^t K_s ds$. However, a general Itô process need not, of course, be a submartingale. However, equation (5) suggests that a similar decomposition exists for more general processes. This is indeed the case. For a generalization covering all Itô processes we relax both the martingale property of M and the

monotonicity of A . In general, A is only required to be of finite variation, that is, the difference of two increasing processes. In the Itô process example, these are $A_t^{(+)} = \int_0^t \max(K_s, 0) ds$ and $A_t^{(-)} = \int_0^t \max(-K_s, 0) ds$. Put differently, the trend may change its direction every now and then.

To cover all Itô processes, one must also allow for local martingales rather than martingales. M is said to be a *local martingale* if there exists a sequence of stopping times $(T_n)_{n \in \mathbb{N}}$, which increases to ∞ almost surely such that M^{T_n} is a martingale for any n . Here, the *stopped process* M^{T_n} is defined as $M_t^{T_n} := M_{\min(T_n, t)}$, that is, it stays constant after time T_n (as e.g., your wealth does if you sell an asset at T_n). This rather technical concept appears naturally in the general theory of stochastic processes. For example, stochastic integrals $M_t = \int_0^t H_s dN_s$ relative to martingales N generally fail to be martingales but are typically local martingales or a little less, namely, *σ -martingales*.

A local martingale is a uniformly integrable martingale, if and only if it is of class (D). Nevertheless, one should be careful with thinking that local martingales behave basically as martingales up to some integrability. For example, there exist local martingales $M_t = \int_0^t H_s dW_s$ with $M_0 = 0$ and $M_1 = 1$ a.s. and such that $E(|M_t|) < \infty$, $t \geq 0$. Even though such a process has no trend in a local sense, it behaves entirely differently from a martingale on a global scale. The difference between local martingales and martingales leads to many technical problems in mathematical finance. For example, the previous example may be interpreted in the sense that dynamic investment in a perfectly reasonable martingale may lead to arbitrage unless the set of trading strategies is restricted to some admissible subset.

Let us come back to generalizing the Doob–Meyer decomposition. Without class (D) it reads as follows:

Theorem 2 *Any submartingale X allows for a unique decomposition (4) with a local martingale M and some predictable increasing process A satisfying $A_0 = 0$.*

For a considerably larger class of processes X , there exists a *canonical decomposition* (4) with a local martingale M and some predictable process A of finite variation, which starts in 0. These processes are called *special semimartingales* and they play a key role in stochastic calculus. The slightly larger

class of *semimartingales* is obtained, if A is only required to be adapted rather than predictable. This class is, in some sense, the largest one that allows for the definition of a stochastic integral $\int_0^t H_s dX_s$ satisfying a mild continuity property. In the general **semimartingale** case, decomposition (4) should not be called canonical because it is not unique. Moreover, A should not be regarded as a trend unless it is predictable. On the other hand, if the jumps of a semimartingale X are sufficiently integrable (e.g., bounded), then X is special and hence allows for a canonical decomposition resembling the Doob–Meyer decomposition of a submartingale.

Forward–Backward Stochastic Differential Equations (SDEs)

A *forward–backward stochastic differential equation* (FBSDE) is a system of two Itô-type stochastic differential equations (SDEs) over $[0, T]$ taking the following form:

$$\begin{cases} dX_t = b(t, \omega, X_t, Y_t, Z_t)dt \\ \quad + \sigma(t, \omega, X_t, Y_t, Z_t)dW_t, & X_0 = x; \\ dY_t = -f(t, \omega, X_t, Y_t, Z_t)dt + Z_t dW_t, \\ Y_T = g(\omega, X_T) \end{cases} \quad (1)$$

Here W is a standard Brownian motion defined on a complete probability space $(\Omega, \mathcal{F}, P)$, and $\mathbf{F} \triangleq \{\mathcal{F}_t\}_{0 \leq t \leq T}$ is the filtration generated by W augmented with all the null sets. The coefficients b, σ, f, g are progressively measurable; b, σ, f are $\mathbf{F}$ -adapted for fixed (x, y, z) ; and g is $\mathcal{F}_T$ -measurable for fixed x . The first equation is forward because the initial value X_0 is given, while the second one is backward because the terminal condition Y_T is given. The solution to FBSDE (1) consists of three $\mathbf{F}$ -adapted processes (X, Y, Z) that satisfy equation (1) for any t , P almost surely (a.s.), and

$$\begin{aligned} \|(X, Y, Z)\|^2 &\triangleq E \left\{ \sup_{0 \leq t \leq T} [|X_t|^2 + |Y_t|^2] \right. \\ &\quad \left. + \int_0^T |Z_t|^2 dt \right\} < \infty \end{aligned} \quad (2)$$

BSDEs can be traced back to the 1973 paper by Bismut [7], where a linear BSDE is introduced as an adjoint equation for a stochastic control problem. Bensoussan [6] proved the well posedness of general linear BSDEs by using the martingale representation theorem. The general theory of nonlinear BSDEs, however, originated from the seminal work of Pardoux and Peng [37]. Their motivation was to study the general Pontryagin-type maximum principle for stochastic optimal controls; see, for example, [40]. Independent of the development of this theory, Duffie and Epstein [19, 20] proposed the concept of stochastic recursive utility, and it turns out that

BSDEs provide exactly the right mathematical tool for it.

Peng [41], and Pardoux and Peng [38], then studied *decoupled FBSDEs*, that is, b and σ do not depend on (y, z) . They discovered the deep relation between Markovian FBSDEs (i.e., FBSDEs with deterministic coefficients) and PDEs, *via* the so called *nonlinear Feynman–Kac formula*. Soon after that, people found that such FBSDEs had very natural applications in option pricing theory, and thus extended the Black–Scholes formula to a much more general framework. In particular, the solution triplet (X, Y, Z) can be interpreted as the underlying asset price, the option price, and the hedging portfolio, respectively. El Karoui *et al.* [22] further introduced *reflected BSDEs*, which are appropriate for pricing American options, again, in a general framework. See a survey paper [24] and the section Applications for such applications.

The theory of coupled FBSDEs was originally motivated by Black’s consol rate conjecture. Antonelli [1] proved the first well-posedness result, when the time duration T is small. For arbitrary T , there are three typical approaches, each with its limit. The most famous one is the *four-step scheme*, proposed by Ma *et al.* [34]. On the basis of this scheme, Duffie *et al.* [21] confirmed Black’s conjecture. The theory has also been applied to various areas, especially in finance and in stochastic control.

There have been numerous publications on the subject. We refer interested readers to the books [23, 35], and the references therein for the general theory and applications.

Decoupled FBSDEs

Since b and σ do not depend on (y, z) , one can first solve the forward SDE and then the backward one. The main idea in [37] to solve BSDEs is to apply the Picard iteration, or equivalently, the contraction mapping theorem.

Theorem 1 ([38]). *Assume that b, σ do not depend on (y, z) ; that b, σ, f, g are uniformly Lipschitz continuous in (x, y, z) , uniformly on (ω, t) ; and that*

$$\begin{aligned} I_0 &\triangleq E \left\{ \int_0^T \left[|b(t, \cdot, 0)|^2 + |\sigma(t, \cdot, 0)|^2 \right. \right. \\ &\quad \left. \left. + |f(t, \cdot, 0, 0, 0)|^2 \right] dt + |g(\cdot, 0)|^2 \right\} < \infty \end{aligned} \quad (3)$$

Then FBSDE (1) admits a unique solution (X, Y, Z) , and there exists a constant C , depending only on T , the dimensions, and the Lipschitz constant, such that $\|(X, Y, Z)\|^2 \leq C[|x_0|^2 + I_0]$.

When $\dim(Y) = 1$, we have the following comparison result for the BSDE. For $i = 1, 2$, assume (b, σ, f_i, g_i) satisfy the assumptions in Theorem 1 and let (X, Y^i, Z^i) denote the corresponding solutions to equation (1). If $f^1 \leq f^2$, $g^1 \leq g^2$, P a.s., for any (t, x, y, z) , then, $Y_t^1 \leq Y_t^2$, $\forall t$, P a.s.; see, for example, [24]. On the basis of this result, Lepeltier and San Martín [31] constructed solutions to BSDEs with non-Lipschitz coefficients. Moreover, Kobylanski [30] and Briand and Hu [10] proved the well posedness of BSDEs whose generator f has quadratic growth in Z . Such BSDEs are quite useful in practice.

When the coefficients are deterministic, the decoupled FBSDE (1) becomes

$$\begin{cases} dX_t = b(t, X_t)dt + \sigma(t, X_t)dW_t, & X_0 = x; \\ dY_t = -f(t, X_t, Y_t, Z_t)dt + Z_t dW_t, \\ Y_T = g(X_T) \end{cases} \quad (4)$$

In this case, the FBSDE is associated with the following system of parabolic PDEs:

$$\begin{cases} u_t^i + \frac{1}{2} \text{tr} [u_{xx}^i \sigma \sigma^*(t, x)] + u_x^i b(t, x) \\ \quad + f^i(t, x, u, u_x \sigma(t, x)) = 0, \\ i = 1, \dots, m; \\ u(T, x) = g(x) \end{cases} \quad (5)$$

Theorem 2 ([38]). Assume b, σ, f, g satisfy all the conditions in Theorem 1.

- (i) If PDE (5) has a classical solution $u \in C^{1,2}([0, T] \times \mathbb{R}^n)$, then

$$Y_t = u(t, X_t), \quad Z_t = u_x \sigma(t, X_t) \quad (6)$$

- (ii) In general, define

$$u(t, x) \triangleq E\{Y_t | X_t = x\} \quad (7)$$

Then u is deterministic and $Y_t = u(t, X_t)$. Moreover, when $m = 1$, u is the unique viscosity solution to the PDE (5).

In this case, X is a Markov process; then by equation (6) the solution (X, Y, Z) is Markovian. For this

reason we call equation (4) a *Markovian FBSDE*. We note that in the Black–Scholes model, as we see in the section Applications, the PDE (5) is linear and one can solve for u explicitly. Then equation (6) in fact gives us the well known Black–Scholes formula. Moreover, the hedging portfolio $Z_t \sigma^{-1}(t, X_t)$ is the sensitivity of the option price Y_t with respect to the underlying asset price X_t . This is exactly the idea of the Δ -hedging. On the other hand, when f is linear in (y, z) , equation (7) actually is equivalent to the Feynman–Kac formula. In general, when $m = 1$, equation (7) provides a probabilistic representation for the viscosity solution to the PDE (5), and thus is called a *nonlinear Feynman–Kac formula*. Such a type of representation formula is also available for u_x [36].

The link between FBSDEs and PDEs opens the door to efficient Monte Carlo methods for high-dimensional PDEs and FBSDEs, and thus also for many financial problems. This approach can effectively overcome the *curse of dimensionality*; see, for example, [3–5, 8, 27, 45], and [12]. There are also some numerical algorithms for non-Markovian BSDEs and coupled FBSDEs; see, for example, [2, 9, 18, 33], and [17].

Coupled FBSDEs

The theory of coupled FBSDEs is much more complex and is far from complete. There are mainly three approaches for its well posedness, each with its limit. Since the precise statements of the results require complicated notation and technical conditions, we refer readers to the original research papers and focus only on the main ideas here.

Method 1 Contraction Mapping This method works very well for BSDEs and decoupled FBSDEs. However, to ensure the constructed mapping is a contraction one, for coupled FBSDEs one has to assume some stronger conditions. The first well-posedness result was by Antonelli [1], which has been extended further by Pardoux and Tang [39]. Roughly speaking, besides the standard Lipschitz conditions, FBSDE (1) is well posed in one of the following three cases: (i) T is small and either σ_z or g_x is small; (ii) X is weakly coupled into the BSDE (i.e., g_x and f_x are small) or (Y, Z) are weakly coupled into the FSDE (i.e., $b_y, b_z, \sigma_y, \sigma_z$ are small); or (iii) b is deeply decreasing in x (i.e., $[b(\cdot, x_1, \cdot) -$

$b(\cdot, x_2, \cdot)[x_1 - x_2] \leq -C|x_1 - x_2|^2$ for some large C) or f is deeply decreasing in y . Antonelli [1] also provides a counterexample to show that, under Lipschitz conditions only, equation (1) may have no solution.

Method 2 Four-step Scheme This is the most popular method for coupled FBSDEs with deterministic coefficients, proposed by Ma *et al.* [34]. The main idea is to use the close relationship between Markovian FBSDEs and PDEs, in the spirit of Theorem 2. Step 1 in [34] deals with the dependence of σ on z , which works only in very limited cases. The more interesting case is that σ does not depend on z . Then the other three steps read as follows:

Step 2. Solve the following PDE with $u(T, x) = g(x)$: for $i = 1, \dots, m$,

$$\begin{aligned} u_t^i + \frac{1}{2} \text{tr}[u_{xx}^i \sigma \sigma^*(t, x, u)] \\ + u_x^i b(t, x, u, u_x \sigma(t, x, u)) \\ + f^i(t, x, u, u_x \sigma(t, x, u)) = 0 \end{aligned} \quad (8)$$

Step 3. Solve the following FSDE:

$$\begin{aligned} X_t = x + \int_0^t b(s, X_s, u(s, X_s), u_x(s, X_s)) \\ \times \sigma(s, X_s, u(s, X_s)) ds \\ + \int_0^t \sigma(s, X_s, u(s, X_s)) dW_s \end{aligned} \quad (9)$$

Step 4. Set

$$\begin{aligned} Y_t &\triangleq u(t, X_t), Z_t \triangleq u_x(t, X_t) \\ &\times \sigma(t, X_t, u(t, X_t)) \end{aligned} \quad (10)$$

The main result in [34] is essentially the following theorem.

Theorem 3 Assume (i) b, σ, f, g are deterministic, uniformly Lipschitz continuous in (x, y, z) , and σ does not depend on z ; (ii) PDE (8) has a classical solution u with bounded derivatives. Then FBSDE (1) has a unique solution.

This result has been improved by Delarue [16] and Zhang [46], by weakening the requirement on u to only uniform Lipschitz continuity in x . Delarue [16]

assumes some sufficient conditions on the deterministic coefficients to ensure such Lipschitz continuity. In particular, one key condition is that the coefficient σ be uniformly nondegenerate. Zhang [46] allows the coefficients to be random and σ to be degenerate, but assumes all processes are one-dimensional along with some special compatibility condition on the coefficients, so that a similarly defined random field $u(t, \omega, x)$ is uniformly Lipschitz continuous in x .

Method 3 Method of Continuation The idea is that, if an FBSDE is well-posed, then a new FBSDE with slightly modified coefficients is also well-posed. The problem is then to find sufficient conditions so that this modification procedure can go arbitrarily long. This method allows the coefficients to be random and σ to be degenerate. However, it requires some monotonicity conditions; see for example, [29, 42], and [43]. For example, [29] assumes that, for some constant $\beta > 0$ and for any $\theta_i = (x_i, y_i, z_i)$, $i = 1, 2$,

$$\begin{aligned} [b(t, \omega, \theta_1) - b(t, \omega, \theta_2)][y_1 - y_2] \\ + [\sigma(t, \omega, \theta_1) - \sigma(t, \omega, \theta_2)][z_1 - z_2] \\ - [f(t, \omega, \theta_1) - f(t, \omega, \theta_2)][x_1 - x_2] \\ \geq \beta[|x_1 - x_2|^2 + |y_1 - y_2|^2 \\ + |z_1 - z_2|^2] \end{aligned} \quad (11)$$

$$\begin{aligned} [g(\omega, x_1) - g(\omega, x_2)][x_1 - x_2] \\ \leq -\beta|x_1 - x_2|^2 \end{aligned} \quad (12)$$

Applications

We now present some typical applications of FBSDEs.

1. Option pricing and hedging

Let us consider the standard Black–Scholes model. The financial market consists of two underlying assets, a riskless one B_t and a risky one S_t . Assume an investor holds a portfolio $(x_t, \pi_t)_{0 \leq t \leq T}$, with its wealth $V_t \triangleq x_t B_t + \pi_t S_t$. We say the portfolio is self-financing if $dV_t = x_t dB_t + \pi_t dS_t$; that is, the change

of the wealth is solely due to the change of the underlying assets' prices.

Now consider a European call option with terminal payoff $g(S_T) \triangleq (S_T - K)^+$. We say a self-financing portfolio (x_t, π_t) is a perfect hedge of the option if $V_T = g(S_T)$. Under a no-arbitrage assumption, V_t is the unique fair option price at t . Let r denote the interest rate of B , μ the appreciation rate, and σ the volatility of S . Then (S, V, π) satisfy the following linear FBSDE:

$$\begin{cases} dS_t = S_t[\mu dt + \sigma dW_t], & S_0 = s_0; \\ dV_t = [r(V_t - \pi_t S_t) + \mu \pi_t S_t]dt \\ \quad + \pi_t S_t \sigma dW_t, & V_T = g(S_T) \end{cases} \quad (13)$$

If the borrowing interest rate R is greater than the lending interesting rate r , then the drift term of dV_t becomes $r(V_t - \pi_t S_t)^+ - R(V_t - \pi_t S_t)^- + \mu \pi_t S_t$, and thus the BSDE becomes nonlinear. The coupled FBSDE gives a nice framework for the large investor problem, where the investment may affect the value of S_t . Assume $dS_t = \mu(t, S_t, V_t, \pi_t)dt + \sigma(t, S_t, V_t, \pi_t)dW_t$. Then the system becomes coupled. We refer to [24] and [15] for more detailed exposure.

2. American option and reflected FBSDEs

Consider an American option with generator f , terminal payoff function g , and early exercise payoff L_t . Let X denote the underlying asset price, Y the option price, and $Z\sigma^{-1}$ the hedging portfolio. Then the American option solves the following reflected FBSDE with an extra component K , which is continuous and increasing, with $K_0 = 0$:

$$\begin{cases} dX_t = b(t, \omega, X_t)dt + \sigma(t, \omega, X_t)dW_t, \\ \quad X_0 = x_0; \\ dY_t = -f(t, \omega, X_t, Y_t, Z_t)dt \\ \quad + Z_t dW_t - dK_t, \quad Y_T = g(\omega, X_T); \\ \quad Y_t \geq L_t; \quad [Y_t - L_t]dK_t = 0 \end{cases} \quad (14)$$

Here $K_T - K_t$ can be interpreted as the time value of the option. Moreover, the optimal exercise time is $\tau \triangleq \inf\{t \geq 0 : Y_t = L_t\} \wedge T$. See [22] for more details.

In the Markovian case with $L_t = h(t, X_t)$, the RFBSDE (14) is associated with the following obstacle problem of PDE with $u(T, x) = g(x)$, in the spirit

of Theorem 2:

$$\min \left(u - h(t, x), -u_t - \frac{1}{2} \text{tr}(u_{xx} \sigma \sigma^*(t, x)) - u_x b(t, x) - f(t, x, u, u_x \sigma) \right) = 0 \quad (15)$$

3. Some further extensions

The previous two models consider complete markets. El Karoui and Quenez [26] studied superhedging problems in incomplete markets. They have shown that the superhedging price of a contingent claim is the increasing limit of solutions of a sequence of BSDEs. Cvitanic *et al.* [14] also studied superhedging problems, but in the case that there is a constraint on the portfolio part Z . It turns out that the superhedging price is the minimum solution to an FBSDE with reflection/constraint on Z . Buckdahn and Hu [11] studied a similar problem, but using coupled FBSDE with reflections.

Another application is the zero-sum Dynkin game. The value process Y is the solution to a BSDE with double barriers of Y : $L_t \leq Y_t \leq U_t$. In this case, besides (Y, Z) , the solution consists of two increasing processes K^+, K^- satisfying $[Y_t - L_t]dK_t^+ = [U_t - Y_t]dK_t^- = 0$, and an equilibrium of the game is a pair of stopping times: $\tau_1^* \triangleq \inf\{t : Y_t = L_t\} \wedge T$, $\tau_2^* \triangleq \inf\{t : Y_t = U_t\} \wedge T$. The work in [13, 28] and [32] is along this line.

4. Black's consol rate conjecture

Let r denote the short-rate process and $Y_t \triangleq E_t \left\{ \int_t^\infty \exp \left(- \int_t^s r_l dl \right) ds \right\}$ be the consol price. Assume

$$dr_t = \mu(r_t, Y_t)dt + \alpha(r_t, Y_t)dW_t \quad (16)$$

for some deterministic functions μ, α . The question is whether Y satisfies certain SDEs. Black conjectured that there exists a function A , depending on μ and α , such that $dY_t = [r_t Y_t - 1]dt + A(r_t, Y_t)dW_t$.

The conjecture is confirmed in [21] by using FBSDEs. Assume r is "hidden Markovian," that is, $r_t = h(X_t)$ for some deterministic function h and some Markov process X . Consider the following

FBSDE over infinite horizon:

$$\begin{cases} dX_t = b(X_t, Y_t)dt + \sigma(X_t, Y_t)dW_t, \\ X_0 = x; \\ Y_t = [h(X_t)Y_t - 1]dt + Z_t dW_t, \\ Y_t \text{ is bounded a.s. uniformly in } t \in [0, \infty) \end{cases}$$

The above FBSDE is associated with the following elliptic PDE

$$\frac{1}{2}\sigma^2(x, u)u''(x) + b(x, u)u'(x) - h(x)u(x) + 1 = 0 \quad (17)$$

Assume equation (17) has a bounded classical solution u . Then the Black's conjecture is true with $A(x, y) = \sigma(x, y)u'(x)$.

5. Stochastic control

This is the original motivation to study BSDEs. The classical results in the literature assumed that the diffusion coefficient σ was independent of the control; then the problem was essentially parallel to a deterministic control problem. With the help of BSDEs, one can derive necessary conditions for stochastic control problems in a general framework. To illustrate the idea, we show a very simple example here. We refer readers to [7, 25, 40], and [44] for more details in this aspect.

Assume the state process is

$$X_t = x + \int_0^t \sigma(s, a_s) dW_s \quad (18)$$

where a is the control in some admissible set $\mathcal{A}$. The goal is to find optimal a^* to maximize the utility (or minimize the cost) $J(a) \triangleq E\{g(X_T) + \int_0^T h(t, a_t)dt\}$; that is, we want to find $a^* \in \mathcal{A}$ such that $J(a^*) \geq J(a)$, for all $a \in \mathcal{A}$.

Define an adjoint equation which is a BSDE:

$$Y_t = g'(X_T) - \int_t^T Z_s dW_s \quad (19)$$

Then for any Δa , one can show that

$$\begin{aligned} \nabla J(a, \Delta a) &\triangleq \lim_{\varepsilon \rightarrow 0} \frac{1}{\varepsilon} [J(a + \varepsilon \Delta a) - J(a)] \\ &= E \left\{ \int_0^T [\sigma'(t, a_t) Z_t + h'(t, a_t)] \Delta a_t dt \right\} \end{aligned}$$

where σ', h' are derivatives with respect to a . If a^* is optimal, then $\nabla J(a^*, \Delta a) \leq 0$ for any Δa . As a necessary condition, we obtain the *stochastic maximum principle*:

$$\sigma'(t, a_t^*) Z_t + h'(t, a_t^*) = 0 \quad (20)$$

Under certain technical conditions, we get $a_t^* = I(t, Z_t)$ for some deterministic function I . Plugging this into equations (18) and (19) we obtain a coupled FBSDE.

Martingale Representation Theorem

The “martingale representation theorem” is one of the fundamental theorems of stochastic calculus. It was first noted by Itô [9] (see **Itô, Kiyosi (1915–2008)**) as an application of multiple Wiener–Itô integrals. It was later modified and extended to various forms by many authors, but the basic theme remains the same: a square-integrable (local) martingale with respect to the filtration generated by a Brownian motion can always be represented as an Itô integral with respect to *that* Brownian motion. An immediate consequence would then be that every square-integrable martingale with respect to a *Brownian filtration* must have continuous paths. The martingale representation theorem is particularly useful in fields such as nonlinear filtering and mathematical finance [12] (see **Second Fundamental Theorem of Asset Pricing**) and it is a fundamental building block of the theory of *backward stochastic differential equations* [17, 19] (see **Backward Stochastic Differential Equations**).

To state the martingale representation theorem more precisely, let us consider a probability space $(\Omega, \mathcal{F}, P)$, on which is defined a d -dimensional Brownian motion B . We denote the filtration generated by B as $\mathbf{F}^B \triangleq \{\mathcal{F}_t^B\}_{t \geq 0}$, where $\mathcal{F}_t^B = \sigma\{B_s : s \leq t\} \vee \mathcal{N}$, $t \geq 0$, and $\mathcal{N}$ is the set of all P -null sets in $\mathcal{F}$. It can be checked that the filtration $\mathbf{F}^B$ is *right continuous* (i.e., $\mathcal{F}_t = \mathcal{F}_{t+}^B \triangleq \bigcap_{\varepsilon > 0} \mathcal{F}_{t+\varepsilon}^B$, $t \geq 0$), and $\mathcal{F}_t^B$ contains all P -null sets of $\mathcal{F}$. In other words, $\mathbf{F}^B$ satisfies the so-called usual hypotheses [20] (see **Filtrations**). Let us denote $\mathcal{M}^2(\mathbf{F}^B)$ to be the set of all square-integrable $\mathbf{F}^B$ -martingales and $\mathcal{M}_c^2(\mathbf{F}^B)$ to be the subspace of $\mathcal{M}^2(\mathbf{F}^B)$ of all those martingales that have continuous paths. The most common martingale representation theorem is the following:

Theorem 1 *Let $M \in \mathcal{M}^2(\mathbf{F}^B)$. Then there exists a d -dimensional $\mathbf{F}^B$ -predictable process H with $E \int_0^T |H_s|^2 ds < \infty$ for all $T > 0$, such that*

$$M_t = M_0 + \int_0^t (H_s, dB_s)$$

$$= M_0 + \sum_{i=1}^d \int_0^t H_s^i dB_s^i \quad \forall t \geq 0 \quad (1)$$

Furthermore, the process H is unique modulo $dt \times dP$ -null sets. Consequently, it holds that $\mathcal{M}^2(\mathbf{F}^B) = \mathcal{M}_c^2(\mathbf{F}^B)$.

The proof of this theorem can be found in standard reference books in stochastic analysis, for example, Ikeda and Watanabe [8], Karatzas and Shreve [12], Liptser and Shiryaev [14], Protter [20], and Rogers and Williams [21], to mention a few. But the work of Dellacherie [1] is worth mentioning, since it is the basis for many other proofs in the literature.

Note that if ξ is an $\mathcal{F}_T^B$ -measurable random variable for some $T > 0$ with finite second moments, then $M_t \triangleq E\{\xi | \mathcal{F}_t^B\}$, $t \geq 0$, defines a square-integrable $\mathbf{F}^B$ -martingale. We therefore have the following corollary:

Corollary 1 *Assume that ξ is a $\mathcal{F}_T^B$ -measurable random variable for some $T > 0$, such that $E[|\xi|^2] < \infty$. Then there exists a d -dimensional $\mathbf{F}^B$ -predictable process H with $E \int_0^T |H_s|^2 ds < \infty$ such that*

$$\begin{aligned} \xi &= E[\xi] + \int_0^T (H_s, dB_s) \\ &= E[\xi] + \sum_{i=1}^d \int_0^T H_s^i dB_s^i, \quad P \text{ a.s.} \end{aligned} \quad (2)$$

Furthermore, the process H is unique modulo $dt \times dP$ -null sets.

We remark that in the above corollary, the process H , often referred to as the *martingale integrand* or *representation kernel* of the martingale M , could depend on the duration $T > 0$; therefore, a more precise notation would be $H = H^T$, if the time duration T has to be taken into consideration. But the uniqueness of the representation implies that the family $\{H^T\}$ is actually “consistent” in the sense that $H_t^{T_1} = H_t^{T_2}$, $dt \times dP$ a.e. on $[0, T_1] \times \Omega$, if $T_1 \leq T_2$.

The martingale representation theorem can be generalized to local martingales [12, 20, 21]:

Theorem 2 *Every $\mathbf{F}^B$ -local martingale is continuous and is the stochastic integral with respect to B of*

a predictable process H such that

$$P \left\{ \int_0^t |H_s|^2 ds < \infty : t \geq 0 \right\} = 1 \quad (3)$$

We note that there is a slight difference between Corollary 1 and Theorem 2, on the integrability of the integrand H . In fact, without the local martingale assumption the “local” square integrability such as equation (3) does not guarantee the uniqueness of the process H in Corollary 1. A very elegant result in this regard is attributed to Dudley [4], who proved that any almost surely finite $\mathcal{F}_T$ -measurable random variable ξ can be represented as a stochastic integral evaluated at T , and the “martingale integrand” satisfies only equation (3). However, such representation *does not* have uniqueness. This point was further investigated in [7]. In this study, the filtration is generated by a higher dimensional Brownian motion, of which B is only a part of the components. We also refer to [12] for the discussions on this issue.

Itô’s original martingale representation theorem has been extended to many other situations when the Brownian motion is replaced by certain semimartingales. In this section, we give a brief summary of these cases. For simplicity in what follows, we shall consider only martingales rather than local martingales. The versions for the latter are essentially identical, but with slightly relaxed integrability requirements on the representing integrands, as we saw in Theorem 2.

Representation under Non-Brownian Filtrations

We recall that one of the most important assumptions in the martingale representation theorems is that the filtration is generated by the Brownian motion (or “Brownian-filtration”). When this assumption is removed, the representation may still hold, but the form will change. There are different ways to adjust the result:

1. Fix the probability space, but change the form of representation (by adding an orthogonal martingale).
2. Fix the probability space, but use more information of the martingale to be represented.
3. Extend the probability space, but keep the form of the representation.

The generalization of type (1) essentially uses the idea of orthogonal decomposition of the Hilbert space. In fact, note that $\mathcal{M}^2(\mathbf{F})$ is a Hilbert space, and let $\mathcal{H}$ denote all $H \in \mathcal{M}^2(\mathbf{F})$ such that $H_t = \int_0^t \Phi_s dB_s$, $t \geq 0$ for some progressively measurable process $\Phi \in L^2([0, T] \times \Omega)$. Then $\mathcal{H}$ is a closed subspace of $\mathcal{M}^2(\mathbf{F})$; thus for any $M \in \mathcal{M}^2(\mathbf{F})$ the following decomposition holds:

$$\begin{aligned} M_t &= M_0 + H_t + N_t \\ &= M_0 + \int_0^t \Phi_s dB_s + N_t, \quad t \geq 0 \end{aligned} \quad (4)$$

where $N \in \mathcal{N}^\perp$, the subspace of $\mathcal{M}^2(\mathbf{F})$ consisting of all martingales that are “orthogonal” to $\mathcal{H}$. We refer to [12] and [20], for example, for detailed discussions for this type of representations. The generalizations of types (2) and (3) keep the original form of the representation. We now list two results adapted from Ikeda–Watanabe [8].

Theorem 3 *Let $M^i \in \mathcal{M}_c^2(\mathbf{F})$, $i = 1, 2, \dots, d$. Suppose that $\Phi^{i,j} \in \mathcal{L}^1(\mathbf{F})$ and $\Psi^{i,k} \in \mathcal{L}^2(\mathbf{F})$, $i, j, k = 1, 2, \dots, d$, exist such that for $i, j = 1, 2, \dots, d$,*

$$\begin{aligned} \langle M^i, M^j \rangle_t &= \int_0^t \Phi_s^{ij} ds \quad \text{and} \\ \Phi_s^{i,j} &= \sum_{k=1}^d \Psi_s^{ik} \Psi_s^{jk}, \quad P \text{ a.s.} \end{aligned} \quad (5)$$

and $\det(\Psi_s^{jk}) \neq 0$, a.s., for all $s \geq 0$. Then there exists a d -dimensional $\mathbf{F}$ -Brownian motion $B = \{B_t^1, \dots, B_t^d\} : t \geq 0\}$ such that

$$M_t^i = M_0^i + \sum_{k=1}^d \int_0^t \Psi_s^{ik} dB_s^k, \quad i = 1, 2, \dots, d \quad (6)$$

We remark that the assumption $\det(\Psi_s^{jk}) \neq 0$ in Theorem 3 is quite restrictive, which implies, among other things, that the representing Brownian motion has to have the same dimension as the given martingale (thus the representation kernel is “squared”). This restriction can be removed by allowing the probability space to be enlarged (or *extended*, see [8]).

Theorem 4 Let $M^i \in \mathcal{M}_c^2(\mathbf{F})$, $i = 1, 2, \dots, d$. Suppose that $\Phi^{i,j}, \Psi^{i,k} \in \mathcal{L}^0(\mathbf{F})$, $i, j = 1, 2, \dots, d$, $k = 1, 2, \dots, r$ exist such that for $i, j = 1, 2, \dots, d$ and $k = 1, 2, \dots, r$, $\int_0^t |\Phi_s^{ij}| ds < \infty$ and $\int_0^t |\Psi_s^{ik}|^2 ds < \infty$, $t \geq 0$, P a.s., and that

$$\langle M^i, M^j \rangle_t = \int_0^t \Phi_s^{ij} ds \quad \text{and} \quad \Phi_s^{i,j} = \sum_{k=1}^d \Psi_s^{ik} \Psi_s^{jk}, \quad P \text{ a.s.} \quad (7)$$

Then there exists an extension $(\tilde{\Omega}, \tilde{\mathcal{F}}, \tilde{P}; \tilde{\mathbf{F}})$ of $(\Omega, \mathcal{F}, P; \mathbf{F})$, and a d -dimensional $\tilde{\mathbf{F}}$ -Brownian motion $B = \{B_t^1, \dots, B_t^d : t \geq 0\}$ such that

$$M_t^i = M_0^i + \sum_{k=1}^d \int_0^t \Psi_s^{ik} dB_s^k, \quad i = 1, 2, \dots, d \quad (8)$$

Representation for Discontinuous Martingales

Up to this point, all the representable martingales are, in fact necessarily, continuous. This clearly excludes many important martingales, most notably the compensated Poisson processes. Thus another generalization of the martingale representation theorem is to replace the Brownian motion by Poisson random measure. We refer to Ikeda and Watanabe [8], for example, for the basic notions of Poisson point process and Poisson random measures.

Let p be a Poisson point process (see **Point Processes**) on some state space $(\mathcal{X}, \mathcal{B}(\mathcal{X}))$, where $\mathcal{B}(\mathcal{X})$ stands for the Borel field of $\mathcal{X}$. For each $t > 0$ and $U \in \mathcal{B}(\mathcal{X})$, define the counting measure $N_p(t, U) \triangleq \sum_{s \leq t} \mathbf{1}_U(p(s))$. We assume that the point process p is of class (QL), that is, the compensator $\hat{N}_p(\cdot, U) = E[N_p(\cdot, U)]$ is continuous for each U ; and $\tilde{N}_p(t, U) = N_p(t, U) - \hat{N}_p(t, U)$ is a martingale. Similar to the Brownian case, we can define the filtration generated by p as $\mathcal{F}_t^p \triangleq \sigma\{N_p(s, U) : s \leq t, U \in \mathcal{B}(\mathcal{X})\}$ (or make it right continuous by defining $\tilde{\mathcal{F}}_t^p = \cap_{\varepsilon > 0} \mathcal{F}_{t+\varepsilon}^p$), and denote $\mathbf{F}^p = \{\mathcal{F}_t^p\}_{t \geq 0}$. We then have the following analog of Theorem 1.

Theorem 5 Let $M \in \mathcal{M}^2(\mathbf{F}^p)$. Then there exists an $\mathbf{F}^p$ -predictable random field $f : \Omega \times [0, \infty) \times$

$\mathcal{X} \mapsto \mathbb{R}$ satisfying $E \left\{ \int_0^t \int_{\mathcal{X}} |f(s, x, \cdot)|^2 \hat{N}_p(ds, dx) \right\} < \infty$, such that

$$M_t = M_0 + \int_0^{t+} \int_{\mathcal{X}} f(s, x, \cdot) \tilde{N}_p(ds, dx), \quad t \geq 0 \quad (9)$$

We should note that like Theorem 1, Theorem 5 also has generalizations that could be considered as counterparts of Theorems 3 and 4 [8]. It is worth noting that by combining Theorems 1 and 5, it is possible to obtain a martingale representation theorem that involves both Brownian motion and the Poisson random measure. Keeping the Lévy–Khintchine formula (see **Lévy Processes**) (or Lévy–Itô Theorem) in mind, we have the following representation theorem, which is a simplified version resulting from a much deeper and extensive exposition by Jacod and Shiryaev [10] (see also [13]). Let $\mathbf{F}$ be the filtration generated by a Lévy process with the Brownian component B and Poisson component N .

Theorem 6 Suppose that $M \in \mathcal{M}^2(\mathbf{F})$. Then there exist an $\mathbf{F}$ -adapted process H and a random field G satisfying $E \int_0^T |H_s|^2 ds < \infty$, $E \left\{ \int_0^t \int_{\mathbb{R} \setminus 0} |G(s, x)|^2 \tilde{N}(ds, dx) \right\} < \infty$, such that

$$M_t = M_0 + \int_0^t H_s dB_s + \int_0^t \int_{\mathbb{R} \setminus 0} G(s, x) \tilde{N}(ds, dx) \quad (10)$$

Moreover, the elements of the pair (H, G) are unique in their respective spaces.

In Theorem 6, the Brownian component and the Poisson component of the Lévy process have to be treated *separately*, and one *cannot* simply replace the Brownian motion in Theorem 1 by a Lévy process. In fact, the martingale representation for Lévy process is a much more subtle issue, and was recently studied by Nualart and Schoutens [18] via the chaotic representation using the so-called Teugels martingales. We refer also to Løkka [15] for a more recent development on this issue.

A natural question now is whether the martingale representation theorem can still hold (in the usual sense) for martingales with jumps. The answer to this question has an important implication in finance, since, as we shall see subsequently, this is the

same as asking whether a market could be complete when the dynamics of the underlying assets have jumps. It turns out that there indeed exists a class of martingales, known as the *normal martingales*, that are discontinuous in general but the martingale representation theorem holds. A square-integrable martingale M is called *normal* if $\langle M \rangle_t = t$ (cf. [2]). The class of normal martingale, in particular, includes those martingales that satisfy the so-called structure equation (cf. [5, 6]). Examples of normal martingales satisfying the structure equation include Brownian motion, compensated Poisson process, the Azéma martingale, and the “parabolic” martingale [20]. The martingale representation, or more precisely the Clark–Ocone formula, was proved in [16]. The application of such a representation in finance was first done by Dritschel and Protter [3] (see also [11]).

Relation with Hedging

The martingale representation theorem is the basis for the arguments leading to *market completeness*, a fundamental component in the “Second Fundamental Theorem” of mathematical finance (see **Second Fundamental Theorem of Asset Pricing**). Consider a market modeled by a probability space $(\Omega, \mathcal{F}, P, \mathbf{F})$, where $\mathbf{F}$ is the filtration generated by a Brownian motion that represents market randomness, and denote it by B . Assume that the market is arbitrage free; then there exists a risk neutral measure Q (see **Fundamental Theorem of Asset Pricing**), equivalent to P . The arbitrage price at time $t \in [0, T]$ for any contingent T -claim $\mathcal{X}$ is given by the *discounted present value formula*:

$$V_t = e^{-r(T-t)} E^Q[\mathcal{X} | \mathcal{F}_t], \quad t \in [0, T] \quad (11)$$

where r is the (constant) interest rate. If $\mathcal{X}$ is square integrable, then $M_t = e^{-rt} V_t$, $t \geq 0$, is a square-integrable $\mathbf{F}$ -martingale under Q . Applying the martingale representation theorem one has

$$M_t = M_0 + \int_0^t \phi_s dB_s, \quad t \in [0, T] \quad (12)$$

for some square-integrable, $\mathbf{F}$ -predictable process ϕ . Or equivalently, assuming that the volatility of the

market, denoted by σ , is positive, we can write

$$V_t = V_0 + \int_0^t r V_s ds + \int_0^t \pi_t \sigma_s dB_s, \quad t \in [0, T] \quad (13)$$

where $\pi_t = e^{rt} \phi_t \sigma_t^{-1}$, $t \geq 0$. The process π is then exactly the “hedging strategy” for the claim $\mathcal{X}$, that is, the amount of money one should invest in the stock, so that $V_T = \mathcal{X}$, almost surely.

The martingale representation theorem also plays an important role in portfolio optimization problems, especially in finding optimal strategies [12].

One of the abstract forms of the hedging problem described earlier is the so-called backward stochastic differential equation (BSDE), which is the problem of finding a pair of $\mathbf{F}$ -adapted processes (V, Z) so that the following *terminal value problems* for a stochastic differential equation similar to (13) holds:

$$\begin{aligned} dV_t &= f(t, V_t, Z_t) dt + Z_t dB_t, \quad t \in [0, T] \\ V_T &= \mathcal{X} \end{aligned} \quad (14)$$

See **Forward–Backward Stochastic Differential Equations (SDEs); Backward Stochastic Differential Equations**.

Backward Stochastic Differential Equations

Backward stochastic differential equations (BSDEs) occur in situations where the terminal (as opposed to the initial) condition of stochastic differential equations is a given random variable. Linear BSDEs were first introduced by Bismut (1976) as the adjoint equation associated with the stochastic version of the Pontryagin maximum principle in control theory. The general case of a nonlinear BSDE was first introduced by Peng and Pardoux [23] to give a Feynman–Kac representation of nonlinear parabolic partial differential equations (PDEs). The solution of a BSDE consists of a pair of adapted processes (Y, Z) satisfying

$$-dY_t = f(t, Y_t, Z_t)dt - Z'_t dW_t, \quad Y_T = \xi \quad (1)$$

where f is called the *driver* and ξ the *terminal condition*. This type of equation appears naturally in hedging problems. For example, in a complete market (see **Complete Markets**), the price process $(Y_t)_{0 \leq t \leq T}$ of a European contingent claim ξ with maturity T corresponds to the solution of a BSDE with a linear driver f and a terminal condition equal to ξ .

Reflected BSDEs were introduced by El Karoui *et al.* [6]. In the case of a reflected BSDE, the solution Y is constrained to be greater than a given process called the *obstacle*. A nondecreasing process K is introduced in the equation in order to push (upward) the solution so that the constraint is satisfied, and this push is minimal, that is, Y satisfies the following equation:

$$-dY_t = f(t, Y_t, Z_t)dt + dK_t - Z'_t dW_t, \quad Y_T = \xi \quad (2)$$

with $(Y_t - S_t) dK_t = 0$. One can show that the price of an American option (with eventually some non-linear constraints) is the solution of a reflected BSDE, where the obstacle is given by the payoff process.

Definition and Properties

We adopt the following notation: $\mathcal{IF} = \{\mathcal{F}_t, 0 \leq t \leq T\}$ is the natural filtration of an n -dimensional

Brownian motion W ; L^2 is the set of random variables ξ that are $\mathcal{F}_T$ -measurable and square-integrable; $\mathcal{IH}^2$ is the set of predictable processes ϕ such that $E \int_0^T |\phi_t|^2 dt < \infty$. In the following, the sign $'$ denotes transposition.

Let us consider the following BSDE (with dimension 1 to simplify the presentation):

$$-dY_t = f(t, Y_t, Z_t)dt - Z'_t dW_t, \quad Y_T = \xi \quad (3)$$

where $\xi \in L^2$ and f is a *driver*, that is, it satisfies the following assumptions: $f : \Omega \times [0, T] \times \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}$ est $\mathcal{P} \otimes \mathcal{B} \otimes \mathcal{B}^n$ -measurable, $f(\cdot, 0, 0) \in \mathcal{IH}^2$ and f is uniformly Lipschitz with respect to y, z with constant $C > 0$. Such a pair (ξ, f) is called a pair of *standard parameters*. If the driver f does not depend on y and z , the solution Y of equation (3) is then given as

$$Y_t = E \left[\xi + \int_t^T f(s) ds / \mathcal{F}_t \right] \quad (4)$$

and the martingale representation theorem for Brownian motion ([16] Theorem 4.15) gives the existence of a unique process $Z \in \mathcal{IH}^2$ such that

$$E \left[\xi + \int_0^T f(s) ds / \mathcal{F}_t \right] = Y_0 + \int_0^t Z'_s dW_s \quad (5)$$

In 1990, Peng and Pardoux [23] stated the following theorem.

Theorem 1 *If $\xi \in L^2$ and if f is a driver, then there exists a unique pair of solutions $(Y, Z) \in \mathcal{IH}^2 \times \mathcal{IH}^2$ of equation (3).*

In [7], El Karoui *et al.* have given a short proof of this theorem based on *a priori estimations* of the solutions. More precisely, the proposition is given as follows:

Proposition 1 (A Priori Estimations). *Let f^1, ξ^1, f^2, ξ^2 be standard parameters. Let (Y^1, Z^1) be the solution associated with f^1, ξ^1 and (Y^2, Z^2) be the solution associated with f^2, ξ^2 . Let C be the Lipschitz constant of f^1 . Substitute $\delta Y_t = Y_t^1 - Y_t^2, \delta Z_t = Z_t^1 - Z_t^2$, and $\delta_2 f_t = f^1(t, Y_t^2, Z_t^2) - f^2(t, Y_t^2, Z_t^2)$. For (λ, μ, β) such that $\lambda^2 > C$ and β sufficiently*

large, that is, $\beta > C(2 + \lambda^2) + \mu^2$, the following estimations hold:

$$\|\delta Y\|_\beta^2 \leq T \left[e^{\beta T} E(|\delta Y_T|^2) + \frac{1}{\mu^2} \|\delta_2 f\|_\beta^2 \right] \quad (6)$$

$$\|\delta Z\|_\beta^2 \leq \frac{\lambda^2}{\lambda^2 - C} \left[e^{\beta T} E(|\delta Y_T|^2) + \frac{1}{\mu^2} \|\delta_2 f\|_\beta^2 \right] \quad (7)$$

where $\|\delta Y\|_\beta^2 = E \int_0^T e^{\beta t} |\delta Y_t|^2 dt$.

From these estimations, *uniqueness* and *existence* of a solution follow by using the fixed point theorem applied to the function $\Psi : \mathbb{H}_\beta^2 \otimes \mathbb{H}_\beta^2 \rightarrow \mathbb{H}_\beta^2 \otimes \mathbb{H}_\beta^2; (y, z) \mapsto (Y, Z)$, where (Y, Z) is the solution associated with the driver $f(t, y_t, z_t)$ and $\mathbb{H}_\beta^2$ denotes the space $\mathbb{H}^2$ endowed with norm $\|\cdot\|_\beta$. Indeed, by using the previous estimations, one can show that for sufficiently large β , the mapping Ψ is strictly contracting, which gives the existence of a unique fixed point, which is the solution of the BSDE.

In addition, from “*a priori* estimations” (Proposition 1), some *continuity* and *differentiability* of solutions of BSDEs (with respect to some parameter) can be derived ([7] section 2).

Furthermore, estimations (1) are also very useful to derive some results concerning approximation or discretization of BSDEs [14].

Recall the dependence of the solutions of BSDEs with respect to terminal time T and terminal condition ξ by the notation $(Y_t(T, \xi), Z_t(T, \xi))$. We have the following flow property.

Proposition 2 (Flow Property). *Let $(Y(T, \xi), Z(T, \xi))$ be the solution of a BSDE associated with the terminal time $T > 0$ and standard parameters (ξ, f) .*

For any stopping time $S \leq T$,

$$\begin{aligned} Y_t(T, \xi) &= Y_t(S, Y_S(T, \xi)), \\ Z_t(T, \xi) &= Z_t(S, Y_S(T, \xi)), \\ t &\in [0, S], \quad dP \otimes dt\text{-almost surely} \end{aligned} \quad (8)$$

Proof By conventional notation, we define the solution of the BSDE with terminal condition (T, ξ) for $t \geq T$ by $(Y_t = \xi, Z_t = 0)$. Thus, if $T' \geq T$, then $((Y_t, Z_t); t \leq T')$ is the unique solution of the BSDE with terminal time T' , coefficient $f(t, y, z)\mathbf{1}_{[t \leq T]}$, and terminal condition ξ .

Let $S \leq T$ be a stopping time, and denote by $Y_t(S, \xi')$ the solution of the BSDE with terminal time T , coefficient $f(t, y, z)\mathbf{1}_{[t \leq S]}$, and terminal condition ξ' ($\mathcal{F}_S$ -measurable). Both the processes $(Y_t(S, Y_S), Z_t(S, Y_S); t \in [0, T])$ and $(Y_{t \wedge S}(T, \xi), Z(T, \xi)\mathbf{1}_{[t \leq S]}; t \in [0, T])$ are solutions of the BSDE with terminal time T , coefficient $f(t, y, z)\mathbf{1}_{[t \leq S]}$, and terminal condition Y_S . By uniqueness, these processes are the same $dP \otimes dt$ -a.s.

The simplest case is that of a *linear* BSDE. Let (β, γ) be a bounded $(\mathbb{R}, \mathbb{R}^n)$ -valued predictable process and let $\varphi \in \mathbb{H}^2(\mathbb{R})$, $\xi \in \mathbb{L}^2(\mathbb{R})$. We consider the following BSDE:

$$\begin{aligned} -dY_t &= (\varphi_t + Y_t \beta_t + Z_t' \gamma_t) dt - Z_t' dW_t, \\ Y_T &= \xi \end{aligned} \quad (9)$$

By applying Itô's formula to $\Gamma_t Y_t$, it can easily be shown that the process $\Gamma_t Y_t + \int_0^t \Gamma_s \varphi_s ds$ is a local martingale and even a uniformly integrable martingale, which gives the following proposition.

Proposition 3 *The solution (Y, Z) of the linear BSDE (9) satisfies*

$$\Gamma_t Y_t = E \left[\xi \Gamma_T + \int_t^T \Gamma_s \varphi_s ds \mid \mathcal{F}_t \right] \quad (10)$$

where Γ is the adjoint process (corresponding to a change of numéraire or a deflator in finance) defined by $d\Gamma_t = \Gamma_t[\beta_t dt + \gamma_t^* dW_t]$, $\Gamma_0 = 1$.

Remark 1 First, it can be noted that if ξ and φ are positive, then the process Y is positive. Second, if in addition $Y_0 = 0$ a.s., then for any t , $Y_t = 0$ a.s. and $\varphi_t = 0$ $dt \otimes dP$ -a.s.

From the first point in this remark, one can derive the classical *comparison theorem*, which is a key property of BSDEs.

Theorem 2 (Comparison Theorem). *If f^1, ξ^1 and f^2, ξ^2 are standard parameters and if (Y^1, Z^1) (respectively (Y^2, Z^2)) is the solution associated with (f^1, ξ^1) (respectively (f^2, ξ^2)) satisfying*

1. $\xi^1 \geq \xi^2$ P -a.s.
2. $\delta_2 f_t = f^1(t, Y_t^2, Z_t^2) - f^2(t, Y_t^2, Z_t^2) \geq 0$ $dt \times dP$ -a.s.
3. $f^1(t, Y_t^2, Z_t^2) \in \mathbb{H}^2$.

Then, we have $Y^1 \geq Y^2$ P -a.s.

In addition, the comparison theorem is strict, that is, on the event $\{Y_t^1 = Y_t^2\}$, we have $\xi_1 = \xi_2$ a.s., $f^1(t, Y_t^1, Z_t^1) = f^2(t, Y_t^2, Z_t^2)$ $ds \times dP$ -a.s. and $Y_s^1 = Y_s^2$ a.s., $t \leq s \leq T$.

Idea of the proof. We denote by δY the spread between those two solutions: $\delta Y_t = Y_t^2 - Y_t^1$ and $\delta Z_t = Z_t^2 - Z_t^1$. The problem is to show that under the above assumptions, $\delta Y_t \geq 0$.

Now, the pair $(\delta Y, \delta Z)$ is the solution of the following LBSDE:

$$\begin{aligned} -d\delta Y_t &= \delta_y f^2(t) \delta Y_t + \delta_z f^2(t) \delta Z_t + \varphi_t dt \\ &\quad - \delta Z_t dW_t, \\ \delta Y_T &= \xi^2 - \xi^1 \end{aligned} \quad (11)$$

where $\delta_y f^2(t) = \frac{f^2(t, Y_t^2, Z_t^2) - f^2(t, Y_t^1, Z_t^1)}{Y_t^2 - Y_t^1}$ if $Y_t^2 - Y_t^1$ is not equal to 0, and 0 otherwise (and the same for $\delta_z f^2(t)$). Now, since the driver f^2 is supposed to be uniformly Lipschitz with respect to (y, z) , it follows that $\delta_y f^2(t)$ and $\delta_z f^2(t)$ are bounded. In addition, φ_t and δY_T are nonnegative. It follows from the first point of Remark (1) that the solution δY_t of the LBSDE (11) is nonnegative. In addition, the second point of Remark (1) gives the *strict comparison theorem*.

From this theorem, we then state a general principle for *minima* of BSDEs [7]: if a driver f can be written as an infimum of a family of drivers f^α and if a random variable ξ can be written as an infimum of random variables ξ^α , then the solution of the BSDE associated with f and ξ can be written as the infimum of the solutions of the BSDEs associated with f^α, ξ^α .

More precisely, we have the following proposition.

Proposition 4 (Minima of BSDEs). *Let $(f, f^\alpha; \alpha \in \mathcal{A})$ be a family of drivers and let $(\xi, \xi^\alpha; \alpha \in \mathcal{A})$ be a family of terminal conditions. Let (Y, Z) be the solution of the BSDE associated with (f, ξ) and let (Y^α, Z^α) be the solution of the BSDE associated with (f^α, ξ^α) . Suppose that there exists a parameter $\bar{\alpha}$ such that*

$$\begin{aligned} f(t, Y_t, Z_t) &= \operatorname{ess\,inf}_{\alpha} f^\alpha(t, Y_t, Z_t) \\ &= \bar{f}(t, Y_t, Z_t), \quad dt \otimes dP\text{-a.s.} \end{aligned} \quad (12)$$

$$\xi = \operatorname{ess\,inf}_{\alpha} \xi^\alpha = \bar{\xi}, \quad P\text{-a.s.} \quad (13)$$

Then,

$$Y_t = \operatorname{ess\,inf}_{\alpha} Y_t^\alpha = \bar{Y}_t, \quad 0 \leq t \leq T, \quad P\text{-a.s.} \quad (14)$$

Proof For each α , since $f(t, Y_t, Z_t) \leq f^\alpha(t, Y_t, Z_t)$ $dt \otimes dP$ -a.s. and $\xi \leq \xi^\alpha$, the comparison theorem gives that $Y_t \leq Y_t^\alpha$ $0 \leq t \leq T$, P -a.s. It follows that

$$Y_t \leq \operatorname{ess\,inf}_{\alpha} Y_t^\alpha, \quad 0 \leq t \leq T, \quad P\text{-a.s.} \quad (15)$$

Now, by assumption, it is clear that $Y_t = \bar{Y}_t$, $0 \leq t \leq T$, P -a.s., which gives that the inequality in (15) is an equality, which ends the proof.

Note also that from the strict comparison theorem, one can derive an *optimality criterium* [7]:

Proposition 5 *A parameter $\bar{\alpha}$ is 0-optimal (i.e., $\min_{\alpha} Y_0^\alpha = Y_0^{\bar{\alpha}}$) if and only if*

$$\begin{aligned} f(s, Y_s, Z_s) &= f^{\bar{\alpha}}(s, Y_s, Z_s) dP \otimes ds\text{-a.s.} \\ \xi &= \bar{\xi} \quad P\text{-a.s.} \end{aligned} \quad (16)$$

The flow property (Proposition 2) of the value function corresponds to the *dynamic programming principle* in stochastic control.

Indeed, using the same notation as in Proposition 2, for any stopping time $S \leq T$,

$$\begin{aligned} Y_t(T, \xi) &= \operatorname{ess\,inf}_{\alpha} Y_t^\alpha(S, Y_S(T, \xi)), \\ 0 \leq t \leq S, \quad P\text{-a.s.} \end{aligned} \quad (17)$$

From the principle on minima of BSDEs (Proposition 4), one can easily obtain some links between BSDEs and *stochastic control* (see, e.g. [10] Section 3 for a financial presentation or [26] for a more classical presentation in stochastic control).

Note, in particular, that if this principle on minima of BSDEs is formulated a bit differently, it can be seen as a *verification theorem* for some stochastic control problem written in terms of BSDEs. More precisely, let $(f^\alpha; \alpha \in \mathcal{A})$ be a family of drivers and let $(\xi^\alpha; \alpha \in \mathcal{A})$ be a family of terminal conditions. Let (Y^α, Z^α) be the solution of the BSDE associated with (f^α, ξ^α) . The value function is defined at time t as

$$\bar{Y}_t = \operatorname{ess\,inf}_{\alpha} Y_t^\alpha, \quad P\text{-a.s.} \quad (18)$$

If there exist standard parameters f and ξ and a parameter $\bar{\alpha}$ such that equation (12) holds, then the value function coincides with the solution of the BSDE associated with (f, ξ) . In other words, $\bar{Y}_t = Y_t$, $0 \leq t \leq T$, P -a.s., where (Y, Z) denotes the solution of the BSDE associated with (f, ξ) . It can be noted that this *verification theorem* generalizes the well-known Hamilton–Jacobi–Bellman–verification theorem, which holds in a Markovian framework.

Indeed, recall that in the *Markovian case*, that is, the case where the driver and the terminal condition are functions of a state process, Peng and Pardoux (1992) have given an interpretation of the solution of a BSDE in terms of a PDE [24]. More precisely, the state process $X^{t,x}$ is a diffusion of the following type:

$$dX_s = b(s, X_s)ds + \sigma(s, X_s)dW_s, \quad X_t = x \quad (19)$$

Then, let us consider $(Y^{t,x}, Z^{t,x})$ solution of the following BSDE:

$$\begin{aligned} -dY_s &= f(s, X_s^{t,x}, Y_s, Z_s)ds - Z_s' dW_s, \\ Y_T &= g(X_T^{t,x}) \end{aligned} \quad (20)$$

where b , σ , f , and g are deterministic functions. In this case, one can show that under quite weak conditions, the solution $(Y_s^{t,x}, Z_s^{t,x})$ depends only on time s and on the state process $X_s^{t,x}$ (see [7] Section 4). In addition, if f and g are uniformly continuous with respect to x and if u denotes the function such that $Y_t^{t,x} = u(t, x)$, one can show (see [24] or [10] p. 226 for a shorter proof) that u is a viscosity solution of the following PDE:

$$\begin{aligned} \partial_t u + \mathcal{L}u(t, x) + f(t, x, u(t, x), \partial_x u \sigma(t, x)) &= 0, \\ u(T, x) &= g(x) \end{aligned} \quad (21)$$

where $\mathcal{L}$ denotes the infinitesimal generator of X (see **Forward–Backward Stochastic Differential Equations (SDEs); Markov Processes**). There are some complementary results concerning the case of a *non-Brownian* filtration (see [1] or [7] Section 5). In addition, some properties of *differentiability* in Malliavin’s sense of the solution of a BSDE can be given [7, 24]. In particular, under some smoothness assumptions on f , the process Z_t corresponds to the Malliavin derivative of Y_t , that is,

$$D_t Y_t = Z_t, \quad dP \otimes dt\text{-a.s.} \quad (22)$$

Many tentatives have been made to relax the Lipschitz assumption on the driver f ; for instance, Lepeltier and San Martín [19] and have proved the existence of a solution for BSDEs with a driver f , which is only *continuous with linear growth* by an approximation method. Kobylanski [17] studied the case of *quadratic* BSDEs [20]. To give some intuition on quadratic BSDEs, let us consider the following simple example:

$$\begin{aligned} -dY_t &= \frac{Z_t^2}{2}dt - Z_t dW_t, \\ Y_T &= \xi \end{aligned} \quad (23)$$

Let us make the exponential change of variable $y_t = e^{Y_t}$. By applying Itô’s formula, we easily derive

$$\begin{aligned} dy_t &= e^{Y_t} Z_t dW_t, \\ y_T &= e^\xi \end{aligned} \quad (24)$$

and hence, if ξ is supposed to be bounded and $Z \in H^2$, we have $y_t = E[e^\xi / \mathcal{F}_t]$. Thus, for quadratic BSDEs, it seems quite natural to suppose that the terminal condition is bounded. More precisely, the following existence result holds [17].

Proposition 6 (Quadratic BSDEs). *If the terminal condition ξ is bounded and if the driver f is linear growth in y and quadratic in z , that is,*

$$|f(t, y, z)| \leq C(1 + |y| + |z|^2) \quad (25)$$

then there exists an adapted pair of processes (Y, Z) , which is the solution of the quadratic BSDE associated with f and ξ such that the process Y is bounded and $Z \in H^2$.

The idea is to make an exponential change of variable $y_t = e^{2CY_t}$ and to show the existence of a solution by an approximation method. More precisely, it is possible to show that there exists a nonincreasing sequence of Lipschitz drivers F^p , which converges to F (where F is the driver of the BSDE satisfied by y_t). Then, one can show that the (nonincreasing) sequence y^p of solutions of classical BSDEs associated with F^p converges to a solution y of the BSDE associated with the driver F and terminal condition $e^{2C\xi}$, which gives the desired result.

BSDE for a European Option

Consider a market model with a nonrisky asset, where price per unit $P_0(t)$ at time t satisfies

$$dP_0(t) = P_0(t)r(t)dt \quad (26)$$

and n risky assets, the price of the i th stock $P_i(t)$ is modeled by the linear stochastic differential equation

$$dP_i(t) = P_i(t) \left[b_i(t)dt + \sum_{j=1}^n \sigma_{i,j}(t)dW_t^j \right] \quad (27)$$

driven by a standard n -dimensional Wiener process $W = (W^1, \dots, W^n)'$, defined on a filtered probability space $(\Omega, \mathcal{F}, P)$. We assume the filtration $\mathcal{F}$ generated by the Brownian W is complete. The probability P corresponds to the objective probability measure. The coefficients $r, b_i, \sigma_{i,j}$ are $\mathcal{F}$ -predictable processes. We denote the vector $b := (b^1, \dots, b^n)'$ by b and the volatility matrix $\sigma := (\sigma_{i,j}, 1 \leq i \leq n, 1 \leq j \leq n)$ by σ . We will assume that the matrix σ_t has full rank for any $t \in [0, T]$. Let $\theta_t = (\theta_t^1, \dots, \theta_t^n)'$ be the classical risk-premium vector defined as

$$\theta_t = \sigma^{-1}(b_t - r_t \mathbf{1}) \text{ } P\text{-a.s.} \quad (28)$$

The coefficients σ, b, θ , and r are supposed to be bounded.

Let us consider a small investor, who can invest in the $n + 1$ basic securities. We denote by (X_t) the wealth process. At each time t , he/she chooses the amount $\pi_i(t)$ invested in the i th stock.

More precisely, a portfolio process is an adapted process $\pi = (\pi_1, \dots, \pi_n)'$ with $\int_0^T |\sigma_t' \pi_t|^2 dt < \infty$, P -a.s.

The strategy is supposed to be self-financing, that is, the wealth process satisfies the following dynamics:

$$dX_t^{x,\pi} = r_t X_t dt + \pi_t' \sigma_t (dW_t + \theta_t dt) \quad (29)$$

Generally, the initial wealth $x = X_0$ is taken as a primitive, and for an initial endowment and portfolio process (x, π) , there exists a unique wealth process X , which is the solution of the linear equation (29) with initial condition $X_0 = x$. Therefore, there exists a one-to-one correspondence between pairs (x, π) and trading strategies (X, π) .

Let T be a strictly positive real, which will be the terminal time of our problem. Let ξ be a European

contingent claim settled at time T , that is, an $\mathcal{F}_T$ -measurable square-integrable random variable (it can be thought of as a contract that pays the amount ξ at time T). By a direct application of BSDE results, we derive that there exists a unique P -square-integrable strategy (X, π) such that

$$\begin{aligned} dX_t &= r_t X_t dt + \pi_t' \sigma_t \theta_t dt + \pi_t' \sigma_t dW_t, \\ X_T &= \xi \end{aligned} \quad (30)$$

X_t is the price of claim ξ at time t and (X, π) is a hedging strategy for ξ .

In the case of constraints such as the case of a borrowing interest rate R_t greater than the bond rate r (see [10] p. 201 and 216 or [7]), the case of taxes [8], or the case of a large investor (whose strategy has an influence on prices, see [10] p. 216), the dynamics of the wealth-portfolio strategy is no longer linear. Generally, it can be written as follows:

$$-dX_t = b(t, X_t, \sigma_t' \pi_t) dt - \pi_t' \sigma_t dW_t \quad (31)$$

where b is a driver (the classical case corresponds to the case where $b(t, x, z) = -r_t x - z' \theta_t$).

Let ξ be a square-integrable European contingent claim. BSDE results give the existence and the uniqueness of a P -square-integrable strategy (X, π) such that

$$\begin{aligned} -dX_t &= b(t, X_t, \sigma_t' \pi_t) dt - \pi_t' \sigma_t dW_t, \\ X_T &= \xi \end{aligned} \quad (32)$$

As in the classical case, X_t is the price of the claim ξ at time t and (X, π) is a hedging strategy of ξ . Also note that, under some smoothness assumptions on the driver b , by equality (22), the hedging portfolio process (multiplied by the volatility) $\pi_t' \sigma_t$ corresponds to the Malliavin derivative $D_t X_t$ of the price process, that is,

$$D_t X_t = \sigma_t' \pi_t, \text{ } dP \otimes dt\text{-a.s.} \quad (33)$$

which generalizes (to the nonlinear case) the useful result stated by Karatzas and Ocone [21] in the linear case. Thus, we obtain a nonlinear *price system* (see [10] p. 209), that is, an application that, for each $\xi \in L^2(\mathcal{F}_T)$ and $T \geq 0$, associates an adapted process $(X_t^b(\xi, T))_{0 \leq t \leq T}$, where $X_t^b(\xi, T)$ denotes the solution of the BSDE associated with the driver b , terminal condition ξ , and terminal time T .

By the comparison theorem, this price system is *nondecreasing* with respect to ξ and satisfies the *no-arbitrage* property:

- A1.** If $\xi^1 \geq \xi^2$ and if $X_t^b(\xi^1, T) = X_t^b(\xi^2, T)$ on an event $A \in \mathcal{F}_t$, then $\xi^1 = \xi^2$ on A .

By the flow property of BSDEs (Proposition 2), it is also *consistent*: more precisely, if S is a stopping time (smaller than T), then for each time t smaller than S , the price associated with payoff ξ and maturity T coincides with the price associated with maturity S and payoff $X_S^b(\xi, T)$, that is,

- A2.** $\forall t \leq S, X_t^b(\xi, T) = X_t^b(X_S^b(\xi, T), S)$.

In addition, if $b(t, 0, 0) \geq 0$, then, by the comparison theorem, the price X^b is positive. At least, if b is sublinear with respect to (x, π) (which is generally the case), then, by the comparison theorem, the price system is *sublinear*. Also note that if $b(t, 0, 0) = 0$, then the price of a contingent claim $\xi = 0$ is equal to 0, that is, $X_t^b(0, T) = 0$ and moreover (see, e.g., [25]), the price system satisfies the *zero-one law* property, that is,

- A3.** $X_t(\mathbf{1}_A \xi, T) = \mathbf{1}_A X_t(\xi, T)$ a.s. for $t \leq T$, $A \in \mathcal{F}_t$, and $\xi \in L^2(\mathcal{F}_T)$.

Furthermore, if b does not depend on x , then the price system satisfies the *translation invariance property*:

- A4.** $X_t(\xi + \xi', T) = X_t(\xi, T) + \xi'$, for any $\xi \in L^2(\mathcal{F}_T)$ and $\xi' \in L^2(\mathcal{F}_t)$.

Intuitively, it can be interpreted as a market with interest rate r equal to zero.

In the case where the driver b is convex with respect to (x, π) (which is generally the case), we have a *variational formulation of the price* of a European contingent claim (see [7] or [10] Prop. 3.8 p. 215). Indeed, by classical properties of convex analysis, b can be written as the maximum of a family of affine functions. More precisely, we have

$$b(t, x, \pi) = \sup_{(\beta, \gamma) \in \mathcal{A}} \{b^{\beta, \gamma}(t, x, \pi)\} \quad (34)$$

where $b^{\beta, \gamma}(t, x, \pi) = B(t, \beta_t, \gamma_t) - \beta_t x - \gamma_t' \pi$, where $B(t, \cdot, \cdot)$ is the polar function of b with respect to x, π , that is,

$$B(\omega, t, \beta, \gamma) = \inf_{(x, \pi) \in \mathbb{R} \times \mathbb{R}^n} [b(\omega, t, x, \pi) + \beta_t(\omega)x + \gamma_t'(\omega)\pi] \quad (35)$$

$\mathcal{A}$ is a bounded set of pairs of adapted processes (β, γ) such that $E \int_0^T B(t, \beta_t, \gamma_t)^2 dt < +\infty$. BSDEs' properties give the following variational formulation:

$$X_t^b = \text{ess sup}_{(\beta, \gamma) \in \mathcal{A}} X_t^{\beta, \gamma} \quad (36)$$

where $X^{\beta, \gamma}$ is the solution of the linear BSDE associated with the driver $b^{\beta, \gamma}$ and terminal condition ξ . In other words, $X^{\beta, \gamma}$ is the classical linear price of ξ in a fictitious market with interest rate β and risk-premium γ . The function B can be interpreted as a *cost* function or a *penalty* function (which is equal to 0 in quite a few examples).

An interesting question that follows is “Under what conditions does a nonlinear price system have a BSDE representation?” In 2002, Coquet *et al.* [3] gave the first answer to this question.

Theorem 3 *Let $X(\cdot)$ be a price system, that is, an application that, for each $\xi \in L^2(\mathcal{F}_T)$ and $T \geq 0$, associates an adapted process $(X_t(\xi, T))_{0 \leq t \leq T}$ that is nondecreasing, which satisfies the no-arbitrage property (A1), time consistency (A2), zero-one law (A3), and translation invariance property (A4).*

Suppose that it satisfies the following assumption:

There exists some $\mu > 0$ such that

$X_0(\xi + \xi', T) - X_0(\xi, T) \leq Y_0^\mu(\xi', T)$, for any $\xi \in L^2(\mathcal{F}_T)$ and ξ' a positive random variable $\in L^2(\mathcal{F}_T)$, where $Y_t^\mu(\xi', T)$ is solution of the following BSDE:

$$-dY_t = \mu|Z_t|dt - Z_t dW_t, \quad Y_T = \xi' \quad (37)$$

Then the price system has a BSDE representation, that is, there exists a standard driver $b(t, z)$ that does not depend on x such that $b(t, 0) = 0$ and that is Lipschitz with respect to z with coefficient μ , such that $X(\xi, T)$ corresponds to the solution of the BSDE associated with the terminal time T , driver b , and terminal condition ξ , for any $\xi \in L^2(\mathcal{F}_T)$, $T \geq 0$, that is, $X(\xi, T) = X^b(\xi, T)$.

In this theorem, the existence of the coefficient μ might be interpreted in terms of risk aversion.

Many nonlinear BSDEs also appear in the case of an *incomplete* market (see **Complete Markets**). For example, the superreplication price of a European contingent claim can be obtained as the limit

of a nondecreasing sequence of penalized prices, which are solutions of nonlinear BSDEs [9, 10]. Another example is given by the pricing a European contingent claim *via* exponential utility maximization in an incomplete market. In this case, El Karoui and Rouge [11] have stated that the price of such an option is the solution of a *quadratic* BSDE. More precisely, let us consider a complete market (see **Complete Markets**) [11] that contains n securities, whose (invertible) volatility matrix is denoted by σ_t . Suppose that only the first j securities are available for hedging and their volatility matrix is denoted by σ_t^1 . The utility function is given by $u(x) = -e^{-\gamma x}$, where $\gamma (\geq 0)$ corresponds to the risk-aversion coefficient. Let ξ be a given contingent claim corresponding to an exercise time T ; in other words, ξ is a bounded $\mathcal{F}_T$ -measurable variable. Let $(X_t(\xi, T))$ (also denoted by (X_t)) be the forward price process defined *via* the exponential utility function as in [11]. By Theorem 5.1 in [11], there exists $Z \in H^2(\mathbb{R}^n)$ such that the pair (X, Z) is solution of the quadratic BSDE:

$$\begin{aligned} -dX_t = & \left\{ -(\eta_t + \sigma_t^{-1} v_t^0) \cdot Z_t + \frac{\gamma}{2} |\Pi(Z_t)|^2 \right\} \\ & \times dt - Z_t dW_t, \quad X_T = \xi \end{aligned} \quad (38)$$

where η is the classical relative risk process, v^0 is a given process [11], and $\Pi(z)$ denotes the orthogonal projection of z onto the kernel of σ_t^1 .

Dynamic Risk Measures

In the same way as in the previous section, some dynamic measures of risk can be induced quite simply by BSDEs (note that time-consistent dynamic risk-measures are otherwise very difficult to deal with).

More precisely, let b be a standard driver. We define a *dynamic risk-measure* ρ^b as follows: for each $T \geq 0$ and $\xi \in L^2(\mathcal{F}_T)$, we set

$$\rho_t^b(\xi, T) = X_t^b(-\xi, T) \quad (39)$$

where $(X_t^b(-\xi, T))$ denotes the solution of the BSDE associated with the terminal condition $-\xi$, terminal time T , and driver $b(t, \omega, x, z)$ [25]. Also note that $\rho_t^b(\xi, T) = -X_t^{\bar{b}}(\xi, T)$, where $\bar{b}(t, x, z) = -b(t, -x, -z)$.

Then, by the results of the previous section, the dynamic risk measure ρ^b is *nonincreasing* and satisfies the *no-arbitrage* property (A1). In addition, the risk measure ρ^b is also *consistent*.

If b is superadditive with respect to (x, z) , then the dynamic risk-measure ρ^b is *subadditive*, that is,

$$\text{For any } T \geq 0, \xi, \xi' \in L^2(\mathcal{F}_T), \rho_t^b(\xi + \xi', T) \leq \rho_t^b(\xi, T) + \rho_t^b(\xi', T).$$

If $b(t, 0, 0) = 0$, then ρ^b satisfies *zero-one law* (A3).

In addition, if b does not depend on x , then the measure of risk satisfies the *translation invariance property* (A4).

In addition, if b is positively homogeneous with respect to (x, z) , then the risk measure ρ^b is *positively homogeneous* with respect to ξ , that is, $\rho^b(\lambda\xi, T) = \lambda\rho^b(\xi, T)$, for each real $\lambda \geq 0$, $T \geq 0$, and $\xi \in L^2(\mathcal{F}_T)$.

If b is convex (respectively, concave) with respect to (x, z) , then ρ^b is concave (respectively, convex) with respect to ξ . Furthermore, if b is concave (respectively, convex), we have a variational formulation of the risk measure ρ^b (similar to the one obtained for nonlinear price systems). Note that in the case where b does not depend on x , this dual formulation corresponds to a famous theorem for convex and translation-invariant risk measures [12] and the polar function B corresponds to the penalty function.

Clearly, Theorem 3 can be written in terms of risk measures. Thus, it gives the following interesting result.

Proposition 7 *Let ρ be a dynamic risk measure, that is, an application that, for each $\xi \in L^2(\mathcal{F}_T)$ and $T \geq 0$, associates an adapted process $(\rho_t(\xi, T))_{\{0 \leq t \leq T\}}$. Suppose that ρ is nonincreasing and satisfies assumptions (A1)–(A4) and that there exists some $\mu > 0$ such that $\rho_0(\xi + \xi', T) - \rho_0(\xi, T) \geq -Y_0^\mu(\xi', T)$, for any $\xi \in L^2(\mathcal{F}_T)$ and ξ' a positive random variable $\in L^2(\mathcal{F}_T)$, where $Y_t^\mu(\xi', T)$ is solution of BSDE (37). Then, ρ can be represented by a backward equation, that is, there exists a standard driver $b(t, z)$, which is Lipschitz with respect to z with coefficient μ , such that $\rho = \rho^b$ a.s.*

Relation with Recursive Utility

Another example of BSDEs in finance is given by *recursive utilities* introduced by Duffie and Epstein [5]. Such a utility function associated with

a consumption rate $(c_t, 0 \leq t \leq T)$ corresponds to the solution of BSDE (3) with terminal condition ξ , which can be interpreted as a terminal reward (which can be a function of terminal wealth) and a driver $f(t, c_t, y)$ depending on the consumption rate c_t . The case of a standard utility function corresponds to a linear driver f of the form $f(t, c, y) = u(c) - \beta_t y$, where u is a nondecreasing and concave deterministic function and β corresponds to the discounted rate.

Note that by BSDE results, we may consider a driver f that depends on the variability process Z_t [7]. The generalized recursive utility is then the solution of the BSDE associated with ξ and $f(t, c_t, y, z)$. The standard utility function can be generalized to the following model first introduced by Chen and Epstein [2]:

$$f(t, c, y, z) = u(c) - \beta_t y - K \cdot |z| \quad (40)$$

where $K = (K_1, \dots, K_n)$ and $|z| = (|z^1|, \dots, |z^n|)$. The constants K_i can be interpreted as risk-aversion coefficients (or ambiguity-aversion coefficients).

By the flow property of BSDEs, recursive utility is *consistent*. In addition, by the comparison theorem, if f is concave with respect to (c, y, z) (respectively, nondecreasing with respect to c), then recursive utility is *concave* (respectively, nondecreasing) with respect to c .

In the case where the driver f is concave, we have a *variational formulation* of recursive utility (first stated in [7]) similar to the one obtained for nonlinear convex price systems (see the previous section). Let $F(t, c_t, \cdot, \cdot)$ be the polar function of f with respect to y, z and let $\mathcal{A}(c)$ be the (bounded) set of pairs of adapted processes (β, γ) such that $E \int_0^T F(t, c_t, \beta_t, \gamma_t)^2 dt < +\infty$. Properties on optimization of BSDEs lead us to derive the following *variational formulation*:

$$Y_t = \text{ess} \inf_{(\beta, \gamma) \in \mathcal{A}} Y_t^{\beta, \gamma} \quad (41)$$

where $Y^{\beta, \gamma}$ is the solution of the linear BSDE associated with the driver $f^{\beta, \gamma}(t, c, x, \pi) := F(t, c, \beta_t, \gamma_t) + \beta_t y + \gamma_t' z$ and the terminal condition ξ . Note that $Y^{\beta, \gamma}$ corresponds to a standard utility function evaluated under a discounted rate $-\beta$ and under a probability Q^γ with density with respect to P given by $Z^\gamma(T) = \exp\left(-\int_0^T \gamma_s' dW_s - \frac{1}{2} \int_0^T |\gamma_s|^2 ds\right)$. Indeed,

we have

$$Y_t^{\beta, \gamma} = E_{Q^\gamma} \left[\int_t^T e^{\int_t^s \beta_u du} F(s, c_s, \beta_s, \gamma_s) ds + e^{\int_t^T \beta_u du} Y \middle| \mathcal{F}_t \right] \quad (42)$$

El Karoui *et al.* [8] considered the optimization problem of a recursive utility with nonlinear constraints on the wealth. By using BSDE techniques, the authors state a maximum principle that gives a necessary and sufficient condition of optimality. The variational formulation can also lead to transform the initial problem into a max-min problem, which can be written as a min-max problem under some assumptions.

Reflected BSDEs

Reflected BSDEs have been introduced by El Karoui *et al.* [6]. For a reflected BSDE, the solution is constrained to be greater than a given process called the *obstacle*.

Let S^2 be the set of predictable processes ϕ such that $E(\sup_t |\phi_t|^2) < +\infty$. We are given a couple of standard parameters, that is, a standard driver $f(t, y, z)$ and a process $\{\xi_t, 0 \leq t \leq T\}$ called the *obstacle*, which is supposed to be continuous on $[0, T]$, adapted, belonging to S^2 and satisfying $\lim_{t \rightarrow T} \xi_t \leq \xi_T$.

A solution of the reflected BSDE associated with f and ξ corresponds to a triplet $(Y, Z, K) \in S^2 \times \mathcal{H}^2 \times S^2$ such that

$$\begin{aligned} -dY_t &= f(t, Y_t, Z_t)dt + dK_t - Z_t' dW_t, \\ Y_T &= \xi_T \end{aligned} \quad (43)$$

with $Y_t \geq \xi_t, 0 \leq t \leq T$ and where K is nondecreasing, continuous, adapted process equal to 0 at time 0 such that $\int_0^T (Y_s - \xi_s) dK_s = 0$. The process K can be interpreted as the minimal push, which allows the solution to stay above the obstacle.

We first give a characterization of the solution (first stated by El Karoui and Quenez [10]). For each $t \in [0, T]$, let us denote the set of stopping times by T_t τ such that $\tau \in [t, T]$ a.s.

For each $\tau \in T_t$, we denote by $(X_s(\tau, \xi_\tau), \pi_s(\tau, \xi_\tau), t \leq s \leq \tau)$ the (unique) solution of the

BSDE associated with the terminal time τ , terminal condition ξ_τ , and coefficient f . We easily derive the following property.

Proposition 8 (Characterization). *Suppose that (Y, Z, K) is solution of the reflected BSDE (43). Then, for each $t \in [0, T]$,*

$$Y_t = X_t(D_t, \xi_{D_t}) = \operatorname{ess\,sup}_{\tau \in T_t} X_t(\tau, \xi_\tau) \quad (44)$$

where $D_t = \inf\{u \geq t; Y_u = \xi_u\}$.

Proof By using the fact that $Y_{D_t} = \xi_{D_t}$ and since the process K is constant on $[t, D_t]$, we easily derive that $(Y_s, t \leq s \leq D_t)$ is the solution of the BSDE associated with the terminal time D_t , terminal condition ξ_{D_t} , and coefficient f , that is,

$$Y_t = X_t(D_t, \xi_{D_t}) \quad (45)$$

It remains now to show that $Y_t \geq X_t(\tau, \xi_\tau)$, for each $\tau \in T_t$.

Fix $\tau \in T_t$. On the interval $[t, \tau]$, the pair (Y_s, Z_s) satisfies

$$\begin{aligned} -dY_s &= f(s, Y_s, Z_s)ds + dK_s - Z_s dW_s, \\ Y_\tau &= Y_t \end{aligned} \quad (46)$$

In other words, the pair $(Y_s, Z_s, t \leq s \leq D_t)$ is the solution of BSDE associated with the terminal time τ , terminal condition Y_τ , and coefficient

$$f(s, y, z) + dK_s$$

Since $f(s, y, z) + dK_s \geq f(s, y, z)$ and since $Y_\tau \geq \xi_\tau$, the comparison theorem for BSDEs gives

$$Y_t \geq X_t(\tau, \xi_\tau) \quad (47)$$

and the proof is complete.

Proposition 8 gives the uniqueness of the solution:

Corollary 1 (Uniqueness). *There exists a unique solution of reflected BSDE(43).*

In addition, from Proposition 8 and the comparison theorem for classical BSDEs, we quite naturally derive the following comparison theorem for RBSDEs (see [6] or [18] for a shorter proof).

Proposition 9 (Comparison). *Let ξ^1, ξ^2 be two obstacle processes and let f^1, f^2 be two coefficients.*

Let (Y^1, Z^1, K^1) (respectively, (Y^2, Z^2, K^2)) be a solution of the reflected BSDE (43) for (ξ^1, f^1) (respectively, for (ξ^2, f^2)) and assume that

- $\xi^1 \leq \xi^2$ a.s.
 - $f^1(t, y, z) \leq f^2(t, y, z), \quad t \in [0, T], (y, z) \in \mathbb{R} \times \mathbb{R}^d$.
- Then, $Y_t^1 \leq Y_t^2 \quad \forall t \in [0, T]$ a.s.*

As in the case of classical BSDEs, some *a priori estimations* similar to equations (6) and (7) can be given [6]. From these estimations, we can derive the existence of a solution, that is, the following theorem.

Theorem 4 *There exists a unique solution (Y, Z, K) of RBSDE (43).*

Sketch of the proof. The arguments are the same as in the classical case. The only problem is to show the existence of a solution in the case where the driver f does not depend on y, z . However, this problem is already solved by optimal stopping time theory. Indeed, recall that by Theorem (4), we have Y that is a solution of the RBSDE associated with the driver $f(t)$ and obstacle ξ ; then,

$$\begin{aligned} Y_t &= \operatorname{ess\,sup}_{\tau \in T_t} X(\tau, \xi_\tau) \\ &= \operatorname{ess\,sup}_{\tau \in T_t} E \left[\int_t^\tau f(s) ds + \xi_\tau \middle| \mathcal{F}_t \right] \end{aligned} \quad (48)$$

Thus, to show the existence of a solution, a natural candidate is the process

$$\bar{Y}_t = \operatorname{ess\,sup}_{\tau \in T_t} E \left[\int_t^\tau f(s) ds + \xi_\tau \middle| \mathcal{F}_t \right] \quad (49)$$

Then, by using classical results of the Snell envelope theory, we derive that there exist a nondecreasing continuous process K and an adapted process Z such that $(\bar{Y}, Z, K)$ is the solution of the RBSDE associated with f and ξ .

Remark 2 The existence of a solution of the reflected BSDE can also be derived by an approximation method *via penalization* [6]. Indeed, one can show that the sequence of penalized processes $(Y^n, n \in \mathbb{N})$, defined as the solutions of classical

BSDEs

$$\begin{aligned} -dY_t^n &= f(t, Y_t^n, Z_t^n)dt \\ &\quad + n(Y_t^n - S_t)^- dt - Z_t^n dW_t, \quad Y_T^n = \xi \end{aligned} \quad (50)$$

is nondecreasing (by the comparison theorem) and that it converges a.s. to the solution Y of the reflected BSDE.

In the *Markovian case* [6], that is, in the case where the driver and the obstacle are functions of a state process, we can give an interpretation of the solution of the reflected BSDE in terms of an obstacle problem. More precisely, the framework is the same as in the case of a Markovian BSDE. The state process $X^{t,x}$ follows the dynamics (19). Let $(Y^{t,x}, Z^{t,x}, K^{t,x})$ be the solution of the reflected BSDE:

$$\begin{aligned} -dY_s &= f(s, X_s^{t,x}, Y_s, Z_s)ds + dK_s - Z_s' dW_s, \\ Y_T &= g(X_T^{t,x}) \end{aligned} \quad (51)$$

with $Y_s \geq \xi_s := h(s, X_s^{t,x})$, $t \leq s \leq T$. Moreover, we assume that $h(T, x) \leq g(x)$ for $x \in \mathbb{R}^d$. The functions f, h are deterministic and satisfy

$$h(t, x) \leq K(1 + |x|^p), \quad t \in [0, T], \quad x \in \mathbb{R}^d \quad (52)$$

In this case, if u denotes the function such that $Y_t^{t,x} = u(t, x)$, we have the following theorem.

Theorem 5 *Suppose that the coefficients f, b, σ , and h are jointly continuous with respect to t and x . Then, the function $u(t, x)$ is a viscosity solution of the following obstacle problem:*

$$\begin{aligned} \min((u - h)(t, x), -\partial_t u - \mathcal{L}u - f(t, x, u(t, x), \\ \partial_x u \sigma(t, x))) = 0, \quad u(T, x) = g(x) \end{aligned} \quad (53)$$

Idea of the proof. A first proof [6] can be given by using the approximation of the solution Y of the RBSDE by the increasing sequence Y^n of penalized solutions of BSDEs (50). By the previous results on classical BSDEs in the Markovian case, we know that $Y_t^{n,t,x} = u_n(t, x)$ where u_n is the unique viscosity

solution of a parabolic PDE. Thus, we have that $u_n(t, x) \uparrow u(t, x)$ as $n \rightarrow \infty$ and by using classical techniques of the theory of viscosity solutions, it is possible to show that $u(t, x)$ is a viscosity solution of the obstacle problem (53).

Another proof can be given by directly showing that u is a viscosity solution of the obstacle problem [18].

Under quite standard assumptions on the coefficients, there exists a unique viscosity solution (see **Monotone Schemes**) of the obstacle problem (53) [6]. Generalizations of the previous results have been done on reflected BSDEs. Cvitanic and Karatzas [4] have studied reflected BSDEs with two obstacles and their links with stochastic games. Hamadène *et al.* [15] have studied reflected BSDEs with two obstacles with continuous coefficients. Gegout-Petit and Pardoux [13] have studied reflected BSDEs in a convex domain, Ouknine [22] has studied reflected BSDEs with jumps, and finally Kobylanski *et al.* [18] have studied reflected quadratic RBSDEs.

Reflected BSDEs and Pricing of an American Option under Constraints

In this section, we see how these results can be applied to the problem of evaluation of an American option (see, e.g., [10] Section 5.4). The framework is the one that is described in the previous section (a complete market with nonlinear constraints such as a large investor).

Recall that an American option consists, at time t , in the selection of a stopping time $\nu \geq t$ and (once this exercise time is chosen) of a payoff ξ_ν , where $(\xi_t, 0 \leq t \leq T)$ is a continuous adapted process on $[0, T[$ with $\lim_{t \rightarrow T} \xi_t \leq \xi_T$.

Let ν be a fixed stopping time. Then, from the results on classical BSDEs, there exists a unique pair of square-integrable adapted processes $(X(\nu, \xi_\nu), \pi(\nu, \xi_\nu))$ denoted also by (X^ν, π^ν) , satisfying

$$\begin{aligned} -dX_t^\nu &= b(t, X_t^\nu, \pi_t^\nu)dt - (\pi_t^\nu)' dW_t, \quad X_T^\nu = \xi \end{aligned} \quad (54)$$

(To simplify the presentation, σ_t is assumed to be equal to the identity). $X(\nu, \xi_\nu)$ corresponds to the price of a European option of exercise time ν and payoff ξ_ν .

The price of the American option is then given by a right continuous left limited (RCLL) process Y , satisfying for each t ,

$$Y_t = \operatorname{ess\,sup}_{v \in T_t} X_t(v, \xi_v), \quad P\text{-p.s.} \quad (55)$$

By the previous results, the price $(Y_t, 0 \leq t \leq T)$ corresponds to the solution of a reflected BSDE associated with the coefficient b and obstacle ξ . In other words, there exists a process $\pi \in \mathbb{H}^2$ and K an increasing continuous process such that

$$\begin{aligned} -dY_t &= b(t, Y_t, \pi_t)dt + dK_t - \pi_t' dW_t, \\ Y_T &= \xi_T \end{aligned} \quad (56)$$

with $Y \geq \xi$ and $\int_0^T (Y_t - \xi_t) dK_t = 0$. In addition, the stopping time $D_t = \inf\{s \geq t / Y_s = \xi_s\}$ is optimal, that is,

$$Y_t = \operatorname{ess\,sup}_{v \in T_t} X(v, \xi_v) = X_t(D_t, \xi_{D_t}) \quad (57)$$

Moreover, by the minimality property of the increasing process K , the process Y corresponds to the surreplication price of the option, that is, the smallest price that allows the surreplication of the payoff.

One can also easily state that the price system $\xi \mapsto Y(\xi)$ is nondecreasing and sublinear if b is sublinear with respect to x, π . Note (see [10] p. 239) that the nonarbitrage property holds only in a weak sense: more precisely, let ξ and ξ' be two payoffs and let Y and Y' their associated prices. If $\xi \geq \xi'$ and also $Y_0 = Y'_0$, then $D_0 \leq D'_0$, the payoffs are equal at time D'_0 , and the prices are equal until D'_0 .

In the previous section, we have seen how, in the case where the driver b is convex, one can obtain a variational formulation of the price of a European option. Similarly, one can show that the price of an American option is equal to the *value function of a mixed control problem* [10].

Backward Stochastic Differential Equations: Numerical Methods

Nonlinear backward stochastic differential equations (BSDEs) were introduced in 1990 by Pardoux and Peng [34]. The interest in BSDEs comes from their connections with partial differential equations (PDEs) [14, 38]; stochastic control (see **Stochastic Control**); and mathematical finance (see [16, 17], among others). In particular, as shown in [15], BSDEs are a useful tool in the pricing and hedging of European options. In a complete market, the price process Y of ξ is a solution of a BSDE. BSDEs are also useful in quadratic hedging problems in incomplete markets (see **Mean-Variance Hedging**).

The result that there exist unique BSDE equations under the assumption that the generator is locally Lipschitz can be found in [19]. A similar result was obtained in the case when the coefficient is continuous with linear growth [24]. The same authors, Lepeltier and San Martín [23], generalized these results under the assumption that the coefficients have a superlinear quadratic growth. Other extensions of existence and uniqueness of BSDE are dealt with in [20, 25, 30]. Stability of solutions for BSDE have been studied, for example, in [1], where the authors analyze stability under disturbances in the filtration. In [6], the authors show the existence and uniqueness of the solution and the link with integral-PDEs (see **Partial Integro-differential Equations (PIDEs)**). An existence theorem for BSDEs with jumps is presented in [25, 36]. The authors state a theorem for Lipschitz generators proved by fixed point techniques [37].

Since BSDE solutions are explicit in only a few cases, it is natural to search for numerical methods approximating the unique solution of such equations and to know the associated type of convergence. Some methods of approximation have been developed.

A four-step algorithm is proposed in [27] to solve equations of forward-backward type, relating the type of approximation to PDEs theory. On the other hand, in [3], a method of random discretization in time is used where the convergence of the method for the solution (Y, Z) needs regularity

assumptions only, but for simulation studies multiple approximations are needed. See also [10, 13, 28] for forward-backward systems of SDE (FBSDE) solutions, [18] for a regression-based Monte Carlo method, [39] for approximating solutions of BSDEs, and [35] for Monte Carlo valuation of American Options.

On the other hand, in [2, 9, 11, 26] the authors replace Brownian motion by simple random walks in order to define numerical approximations for BSDEs. This technique simplifies the computation of conditional expectations involved at each time step.

A quantization (see **Quantization Methods**) technique was suggested in [4, 5] for the resolution of reflected backward stochastic differential equations (RBSDEs) when the generator f does not depend on the control variable z . This method is based on the approximation of continuous time processes on a finite grid, and requires a further estimation of the transition probabilities on the grid.

In [8], the authors propose a discrete-time approximation for approximations of RBSDEs. The L^p norm of the error is shown to be of the order of the time step. On the other hand, a numerical approximation for a class of RBSDEs based on numerical approximations for BSDE and approximations given in [29], can be found in [31, 33].

Recently, work on numerical schemes for jumps is given in [22] and is based on the approximation for the Brownian motion and a Poisson process by two simple random walks. Finally, for decoupled FBSDEs with jumps a numerical scheme is proposed in [7].

Let $\Omega = \mathcal{C}([0, 1], \mathbb{R}^d)$ and consider the canonical Wiener space $(\Omega, \mathcal{F}, \mathbb{P}, \mathcal{F}_t)$, in which $B_t(\omega) = \omega(t)$ is a standard d -dimensional Brownian motion. We consider the following BSDE:

$$Y_t = \xi + \int_t^T f(s, Y_s, Z_s) ds - \int_t^T Z_s dB_s \quad (1)$$

where ξ is a $\mathcal{F}_T$ -measurable square integrable random variable and f is Lipschitz continuous in the space variable with Lipschitz constant L . The solution of equation (1) is a pair of adapted processes (Y, Z) , which satisfies the equation.

Numerical Methods for BSDEs

One approach for a numerical scheme for solving BSDEs is based upon a discretization of the equation

(1) by replacing B with a simple random walk. To be more precise, let us consider the symmetric random walk W^n :

$$W_t^n := \frac{1}{\sqrt{n}} \sum_{k=0}^{c_n(t)} \xi_k^n, \quad 0 \leq t \leq T \quad (2)$$

where $\{\xi_k^n\}_{1 \leq k \leq n}$ is an i.i.d. Bernoulli symmetric sequence. We define $\mathcal{G}_k^n := \sigma(\xi_1^n, \dots, \xi_k^n)$. Throughout this section $c_n(t) = \lfloor nt \rfloor / n$, and ξ^n denotes a square integrable random variable, measurable w.r.t. $\mathcal{G}_n^n$ that should converge to ξ . We assume that W^n and B are defined in the same probability space.

In [26], the authors consider the case when the generator depends only on the variable Y , which makes the analysis simpler. In this situation, the BSDE (1) is given by

$$Y_t = \xi + \int_t^T f(Y_s) ds - \int_t^T Z_s dB_s \quad (3)$$

whose solution is given by

$$Y_t = \mathbb{E} \left(\xi + \int_t^T f(Y_s) ds \middle| \mathcal{F}_t \right) \quad (4)$$

which can be discretized in time with step-size $h = T/n$ by solving a discrete BSDE given by

$$Y_{t_i}^n = \xi^n + \frac{1}{n} \sum_{j=i}^n f(Y_{t_j}^n) - \sum_{j=i}^{n-1} Z_{t_j}^n \Delta W_{t_{j+1}}^n \quad (5)$$

This equation has a unique solution (Y_t^n, Z_t^n) since the martingale W^n has the predictable representation property. It can be checked that solving this equation is equivalent to finding a solution to the following implicit iteration problem:

$$Y_{t_i}^n = \mathbb{E} \left\{ Y_{t_{i+1}}^n + \frac{1}{n} f(Y_{t_i}^n) \middle| \mathcal{G}_i^n \right\} \quad (6)$$

which, due to the adaptedness condition, is equivalent to

$$Y_{t_i}^n - \frac{1}{n} f(Y_{t_i}^n) = \mathbb{E} \left\{ Y_{t_{i+1}}^n \middle| \mathcal{G}_i^n \right\} \quad (7)$$

Furthermore, once $Y_{t_{i+1}}^n$ is determined, $Y_{t_i}^n$ is solved via equation (7) by a fixed point technique:

$$\begin{cases} X^0 = \mathbb{E} \left\{ Y_{t_{i+1}}^n \middle| \mathcal{G}_i^n \right\} \\ X^1 = X^0 + \frac{1}{n} f(X^0) \end{cases} \quad (8)$$

It is standard to show that if f is uniformly Lipschitz in the spatial variable x with Lipschitz constant L (we also assume that f is bounded by R), then the iterations of this procedure will converge to the true solution of equation (7) at a geometric rate L/n . Therefore, in the case where n is large enough, one iteration would already give us the error estimate: $|Y_{t_i}^n - X^1| \leq \frac{LR}{n^2}$, producing a good approximate solution of equation (7). Consequently, the explicit numerical scheme is given by

$$\begin{cases} \hat{Y}_T^n = \xi^n, \hat{Z}_T^n = 0 \\ X_{t_i}^n = \mathbb{E} \left\{ \hat{Y}_{t_{i+1}}^n \middle| \mathcal{G}_i^n \right\} \\ \hat{Y}_{t_i}^n = X_{t_i}^n + \frac{1}{n} f(X_{t_i}^n) \\ \hat{Z}_{t_i}^n = \mathbb{E} \left\{ \left[\hat{Y}_{t_{i+1}}^n + \frac{1}{n} f(\hat{Y}_{t_i}^n) - \hat{Y}_{t_i}^n \right] (\Delta W_{t_{i+1}}^n)^{-1} \middle| \mathcal{G}_i^n \right\} \end{cases} \quad (9)$$

The convergence of $\hat{Y}^n$ to Y is proved in the sense of the Skorohod topology in [9, 26]. In [11], the convergence of the sequence Y^n is established using the tool of convergence of filtrations. See also [3] for the case where f depends on both variables y and z .

Application to European Options

In the Black–Scholes model (see **Black–Scholes Formula**)

$$dS_t = \mu S_t dt + \sigma S_t dB_t \quad (10)$$

which is the continuous version of

$$\frac{S_{t+\Delta t} - S_t}{S_t} \approx \mu \Delta t + \sigma \Delta B_t \quad (11)$$

where the relative return has linear growth plus a random perturbation. σ is called the *volatility* and it is a measure of uncertainty. In this particular case, S has an explicit solution given by the Doleans–Dade exponential

$$S_t = S_0 e^{(\mu - \frac{1}{2}\sigma^2 t) + \sigma B_t} \quad (12)$$

We assume the existence of a riskless asset whose evolution is given by $\beta_t = \beta_0 e^{rt}$, where r is a constant interest rate. Then β satisfies the ODE:

$$\beta_t = \beta_0 + r \int_0^t \beta_s ds \quad (13)$$

A portfolio is a pair of adapted processes (a_t, b_t) that represent the amount of investment in both assets at time t (both can be positive or negative). The wealth process is then given by

$$Y_t = a_t S_t + b_t \beta_t \quad (14)$$

We assume Y is self-financing:

$$dY_t = a_t dS_t + b_t d\beta_t \quad (15)$$

A call option gives the holder the right to buy an agreed quantity of a particular commodity S at a certain time (the expiration date, T) for a certain price (the strike price K). The holder has to pay a fee (called a premium q) for this right. If the option can be exercised only at T , the option is called *European*. If it can be exercised at any time before T , it is called *American*. The main question is, what is the right price for an option? Mathematically, q is determined by the existence of a replication strategy with the initial value q and final value $(S_T - K)^+$; that is, find (a_t, b_t) such that

$$Y_t = a_t S_t + b_t \beta_t \quad Y_T = (S_T - K)^+ \quad Y_0 = q \quad (16)$$

We look for a solution to this problem of the form $Y_t = w(t, S_t)$ with $w(T, x) = (x - K)^+$. Using Itô's formula, we get

$$\begin{aligned} Y_t &= Y_0 + \int_0^t \frac{\partial w}{\partial x} dS_s + \int_0^t \frac{\partial^2 w}{\partial x^2} d[S, S]_s \\ &+ \int_0^t \frac{\partial w}{\partial t} ds = Y_0 + \int_0^t \frac{\partial w}{\partial x} \{ \mu S_s ds + \sigma S_s dB_s \} \\ &+ \int_0^t \frac{1}{2} \frac{\partial^2 w}{\partial x^2} \sigma^2 S_s^2 ds \\ &+ \int_0^t \frac{\partial w}{\partial t} ds = Y_0 + \int_0^t \frac{\partial w}{\partial x} \sigma S_s dB_s \\ &+ \int_0^t \left(\frac{1}{2} \frac{\partial^2 w}{\partial x^2} \sigma^2 S_s^2 + \mu S_s \frac{\partial w}{\partial x} + \frac{\partial w}{\partial t} \right) ds \end{aligned} \quad (17)$$

Using the self-financing property, we obtain

$$\begin{aligned} Y_t &= Y_0 + \int_0^t a_s dS_s + \int_0^t b_s d\beta_s = Y_0 + \int_0^t a_s \{ \mu S_s ds \\ &+ \sigma S_s dB_s \} + \int_0^t b_s d\beta_s = Y_0 + \int_0^t a_s \sigma S_s dB_s \end{aligned}$$

$$+ \int_0^t (r b_s \beta_s + a_s \mu S_s) ds \quad (18)$$

Using the uniqueness in the predictable representation property for Brownian motion (see **Martingale Representation Theorem**), we obtain that

$$\begin{aligned} a_s \sigma S_s &= \sigma S_s \frac{\partial w}{\partial x} \\ r b_s \beta_s + a_s \mu S_s &= \frac{1}{2} \sigma^2 S_s^2 \frac{\partial^2 w}{\partial x^2} + \mu S_s \frac{\partial w}{\partial x} + \frac{\partial w}{\partial t} \\ a_s &= \frac{\partial w}{\partial x}(s, S_s) \\ b_s &= \frac{Y_s - a_s S_s}{\beta_s} \end{aligned} \quad (19)$$

Since $r \frac{(Y_s - a_s S_s)}{\beta_s} \beta_s + a_s \mu S_s = \frac{1}{2} \sigma^2 S_s^2 \frac{\partial^2 w}{\partial x^2} + \mu S_s \frac{\partial w}{\partial x} + \frac{\partial w}{\partial t}$, the equation for w is

$$\begin{aligned} r \frac{\partial w}{\partial t} + \frac{1}{2} \sigma^2 x^2 \frac{\partial^2 w}{\partial x^2} &= -r x \frac{\partial w}{\partial x} + r w \\ w(T, x) &= (x - K)^+ \end{aligned} \quad (20)$$

The solution of this PDE is related to a BSDE, which we deduce now. Let us start again from the self-financing assumption

$$\begin{aligned} (S_T - K)^+ &= Y_T = Y_t + \int_t^T \frac{\partial w}{\partial x} dS_s \\ &+ \int_t^T r \left(Y_s - S_s \frac{\partial w}{\partial x} \right) ds = Y_t \\ &+ \int_t^T \sigma S_s \frac{\partial w}{\partial x} dB_s \\ &+ \int_t^T \left(r Y_s + (\mu - r) S_s \frac{\partial w}{\partial x} \right) ds \end{aligned} \quad (21)$$

from which we deduce

$$Y_t = \xi + \int_t^T (\alpha Z_s - r Y_s) ds - \int_t^T Z_s dB_s \quad (22)$$

with $\alpha = \frac{r-\mu}{\sigma}$, $\xi = (S_0 e^{(\mu - \frac{1}{2}\sigma^2 T) + \sigma B_T} - K)^+$, and $Z_s = \sigma S_s \frac{\partial w}{\partial x}$. In this case, we have an explicit solution for w given by

$$Y_0 = S_0 \Phi(g(T, S_0)) - K e^{-rT} \Phi(h(T, S_0)) \quad (23)$$

$$w(t, x) = x \Phi(g(T-t, x)) - K e^{-r(T-t)} \Phi(h(T-t, x)) \quad (24)$$

where $g(t, x) = \frac{\ln(x/K) + (r+1/2\sigma^2)t}{\sigma\sqrt{t}}$, $h(t, x) = g(t, x) - \sigma\sqrt{t}$ and $\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{y^2}{2}} dy$ is the standard normal distribution. In general, for example, when σ may depend on time and (S_t) , we obtain a BSDE for (Y_t) coupled with a forward equation for (S_t) , that can be solved numerically.

Numerical Methods for RBSDEs

In this section, we are interested in the numerical approximation of BSDEs with reflection (in short, RBSDEs). We present here the case of one lower barrier, which we assume is an Itô process (a sum of a Brownian martingale and a continuous finite variation process).

$$\begin{aligned} Y_t &= \xi + \int_t^T f(s, Y_s, Z_s) ds \\ &\quad - \int_t^T Z_s dB_s + K_T - K_t \quad 0 \leq t \leq T \quad (25) \\ Y_t &\geq L_t, \quad 0 \leq t \leq T, \quad \text{and} \quad \int_0^T (Y_t - L_t) dK_t = 0 \quad (26) \end{aligned}$$

where, as before, f is the generator, ξ is the terminal condition, and $L = (L_t)$ is the reflecting barrier. Under the Lipschitz assumption of f (see [14] and for generalizations see [12, 21, 32]) there is a unique solution (Y, Z, K) of adapted processes, with the condition that K is increasing and minimal in the sense that it is supported at the times Y touches the boundary.

The numerical scheme for RBSDEs that we present here is based on a penalization of equation

(26) [14] coupled with a use of the standard Euler scheme. The penalization equation is given by

$$\begin{aligned} Y_t^\varepsilon &= \xi + \int_t^1 f(s, Y_s^\varepsilon, Z_s^\varepsilon) ds \\ &\quad - \int_t^1 Z_s^\varepsilon dB_s + \frac{1}{\varepsilon} \int_t^1 (L_s - Y_s^\varepsilon)^+ ds \end{aligned} \quad (27)$$

In this framework, we define

$$K_t^\varepsilon := \frac{1}{\varepsilon} \int_0^t (L_s - Y_s^\varepsilon)^+ ds, \quad 0 \leq t \leq 1 \quad (28)$$

where ε is the penalization parameter. In order to have an explicit iteration, we include an extra Picard iteration, and the numerical procedure is then

$$\begin{aligned} Y_{t_i}^{\varepsilon, p+1, n} &= Y_{t_{i+1}}^{\varepsilon, p+1, n} + \frac{1}{n} f(t_i, Y_{t_i}^{\varepsilon, p, n}, Z_{t_i}^{\varepsilon, p, n}) \\ &\quad + \frac{1}{n\varepsilon} (L_{t_i} - Y_{t_i}^{\varepsilon, p, n})^+ - \frac{1}{\sqrt{n}} Z_{t_i}^{\varepsilon, p+1, n} \zeta_{i+1} \end{aligned} \quad (29)$$

$$\begin{aligned} K_{t_{i+1}}^{\varepsilon, p+1, n} - K_{t_i}^{\varepsilon, p+1, n} &:= \frac{1}{n\varepsilon} \left(S - \check{Y}_{t_i}^{\varepsilon, p+1, n} \right)^+ \\ \text{for } i &\in \{n-1, \dots, 0\} \end{aligned} \quad (30)$$

Theorem 1 *Under the assumptions*

- A1.** f is Lipschitz continuous and bounded;
- A2.** L is assumed to be an Itô process;
- A3.** $\lim_{n \rightarrow +\infty} \mathbb{E} \left[\sup_{s \in [0, T]} |\mathbb{E}[\xi | \mathcal{F}_s] - \mathbb{E}[\xi^n | \mathcal{G}_{c_n(s)}^n]| \right] = 0$

the triplet $(\xi^n, Y^{\varepsilon, p, n}, Z^{\varepsilon, p, n}, K^{\varepsilon, p, n})$ converges in the Skorohod topology toward the solution (ξ, Y, Z, K) of the RBSDE (26) (the order is first $p \rightarrow \infty$, then $n \rightarrow \infty$ and finally $\varepsilon \rightarrow 0$).

A Procedure Based on Ma and Zhang's Method

We now introduce a numerical scheme based on a suggestion given in [29]. The new ingredient is to use a standard BSDE with no reflection and then

impose in the final condition of every step of the discretization that the solution must be above the barrier. Schematically we have

- $Y_1^n := \xi^n$
- for $i = n, n-1, \dots, 1$ let $(\tilde{Y}^n, Z^n)$ be the solution of the BSDE:

$$\tilde{Y}_{t_{i+1}}^n = Y_{t_i}^n + \frac{1}{n} f(s, \tilde{Y}_s^n, Z_s^n) - Z_s^n (W_{t_{i+1}}^n - W_{t_i}^n) \quad (31)$$

- define $Y_{t_{i+1}}^n = \tilde{Y}_{t_{i+1}}^n \vee L_{t_{i+1}}$
- let $K_0^n = 0$ and define $K_{t_i}^n := \sum_{j=1}^i (Y_{t_j}^n - \tilde{Y}_{t_j}^n)$

Clearly K^n is predictable and we have

$$Y_{t_{i-1}}^n = Y_{t_i}^n + \int_{t_{i-1}}^{t_i} f(s, \tilde{Y}_s^n, Z_s^n) ds - \int_{t_{i-1}}^{t_i} Z_s^n dW_s^n + K_{t_i}^n - K_{t_{i-1}}^n \quad (32)$$

Theorem 2 Under the assumptions **A1**, **A2** of Theorem 1 and

$$\lim_{n \rightarrow +\infty} \mathbb{E} \left[\sup_{s \in [0, T]} |\mathbb{E}[\xi | \mathcal{F}_s] - \mathbb{E}[\xi^n | \mathcal{G}_{c_n(s)}^n]| \right]^2 = 0 \quad (33)$$

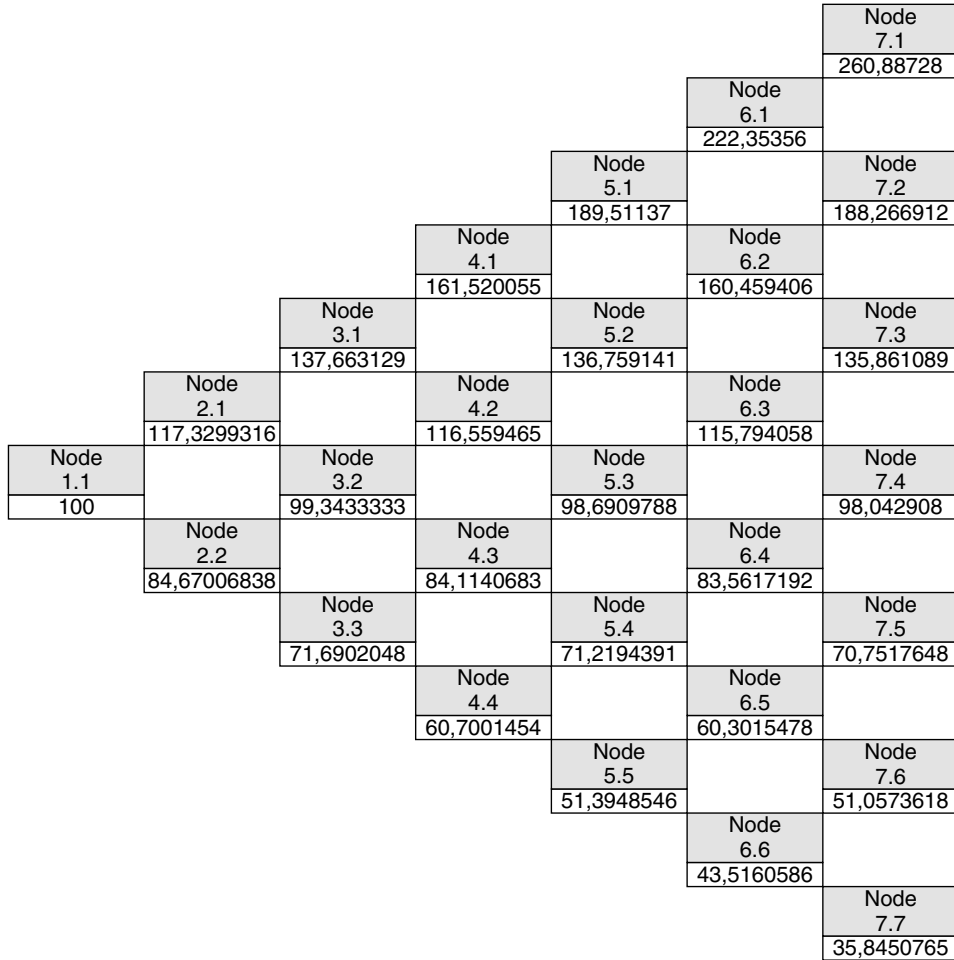

Figure 1 Binomial tree for six time steps, $r = 0.06$, $\sigma = 0.4$, and $T = 0.5$

we have

$$\lim_{n \rightarrow \infty} \mathbb{E} \left[\sup_{0 \leq i \leq n} |Y_{t_i} - Y_{t_i}^n|^2 + \int_0^1 |Z_t - Z_t^n|^2 dt \right] = 0 \quad (34)$$

Application to American Options

An American option (see **American Options**) is one that can be exercised at any time between the purchase date and the expiration date T , which we assume is nonrandom and for the sake of simplicity we take $T = 1$. This situation is more general than the European-style option, which can only be exercised on the date of expiration. Since an American option provides an investor with a greater degree of flexibility, the premium for this option should be higher than the premium for a European-style option.

We consider a financial market described by a filtered probability space $(\Omega, \mathcal{F}, \mathcal{F}_{0 \leq t \leq T}, \mathbb{P})$. As above, we consider the following adapted processes: the price of the risk asset $S = (S_t)_{0 \leq t \leq T}$ and the wealth process $Y = (Y_t)_{0 \leq t \leq T}$. We assume that the rate interest r is constant. The aim is to obtain Y_0 , the value of the American Option.

We assume that there exists a risk-neutral measure (see **Equivalent Martingale Measures**) allowing one to compute prices of all contingent claims as the expected value of their discounted cash flows. The equation that describes the evolution of Y is given by a linear reflected BSDE coupled with the forward equation for S .

$$Y_t = (K - S_t)^+ - \int_t^1 (rY_s + (\mu - r)Z_s) ds + K_1 - K_t - \int_t^1 Z_s dB_s \quad (35)$$

$$S_t = S_0 + \int_0^t \mu S_s ds + \int_0^t \sigma S_s dB_s \quad (36)$$

The increasing process K keeps the process Y above the barrier $L_t = (S_t - K)^+$ (for a call option) in a minimal way, that is, $Y_t \geq L_t$, $dK_t \geq 0$, and

$$\int_0^1 (Y_t - L_t) dK_t = 0 \quad (37)$$

Table 1 Numerical scheme for an American option with 18 steps, $K = 100$, $r = 0.06$, $\sigma = 0.4$, and $T = 0.5$, and different values of S_0

n	$S_0 = 80$	$S_0 = 100$	$S_0 = 120$
1	20	11.2773	4.1187
2	22.1952	10.0171	3.8841
3	21.8707	10.7979	3.1489
4	22.8245	10.1496	3.9042
$\vdots$	$\vdots$	$\vdots$	$\vdots$
15	22.6775	10.8116	3.7119
16	22.6068	10.6171	3.6070
17	22.7144	10.7798	3.6811
18	22.6271	10.6125	3.6364
Real values	21.6059	9.9458	4.0611

The exercise random time is given by the following stopping time $\tau = \inf\{t : Y_t - L_t < 0\}$ that represents the exit time from the market for the investor. As usual, we take $\tau = 1$ if Y never touches the boundary L . At τ the investor will buy the stock if $\tau < 1$, otherwise he/she does not exercise the option. In this problem, we are interested in finding Y_t , Z_t , and τ .

In Table 1 and Figure 1, we summarize the results of a simulation for the American option.

Stochastic Exponential

Let X be a semimartingale with $X_0 = 0$. Then there exists a unique semimartingale Z that satisfies the equation

$$Z_t = 1 + \int_0^t Z_{s-} dX_s \quad (1)$$

It is called the *stochastic exponential* of X and is denoted by $\mathcal{E}(X)$. Sometimes the stochastic exponential is also called the *Doléans exponential*, after the French mathematician Catherine Doléans-Dade. Note that Z_- denotes the left-limit process, so that the integrand in the stochastic integral is predictable.

We first give some examples as follows:

1. If B is a Brownian motion, then an application of Itô's formula reveals that

$$\mathcal{E}(B)_t = \exp\left(B_t - \frac{1}{2}t\right) \quad (2)$$

2. Likewise, the stochastic exponential for a compensated Poisson process $N - \lambda t$ is given as

$$\begin{aligned} \mathcal{E}(N - \lambda t)_t &= \exp\left(-\frac{1}{2}\lambda t\right) \times 2^{N_t} \\ &= \exp\left(\ln(2)N_t - \frac{1}{2}\lambda t\right) \end{aligned} \quad (3)$$

3. The classical Samuelson model for the evolution of stock prices is also given as a stochastic exponential. The price process S is modeled here as the solution of the stochastic differential equation

$$\frac{dS_t}{S_t} = \sigma dB_t + \mu dt \quad (4)$$

Here, we consider the constant trend coefficient μ , the volatility σ , and a Brownian motion B . The solution to this equation is

$$\begin{aligned} S_t &= \mathcal{E}(\sigma B_t + \mu t) \\ &= \exp\left(\sigma B_t + \left(\mu - \frac{1}{2}\sigma^2\right)t\right) \end{aligned} \quad (5)$$

For a general semimartingale X as above, the expression for the stochastic exponential is

$$\begin{aligned} Z_t &= \exp\left(X_t - \frac{1}{2}[X]_t\right) \prod_{0 < s \leq t} (1 + \Delta X_s) \\ &\quad \times \exp\left(-\Delta X_s + \frac{1}{2}(\Delta X_s)^2\right) \end{aligned} \quad (6)$$

where the possibly infinite product converges. Here $[X]$ denotes the *quadratic variation* process of X .

In case X is a local martingale vanishing at zero with $\Delta X > -1$, then $\mathcal{E}(X)$ is a strictly positive local martingale. This property renders the stochastic exponential very useful as a model for asset prices in case the price process is directly modeled under a martingale measure, that is, in the risk neutral world. However, considering some Lévy-process X , many authors prefer to model the price process as $\exp(X)$ rather than $\mathcal{E}(X)$ since this form is better suited for applying Laplace transform methods. In fact, the two representations are equivalent because starting with a model of the form $\exp(X)$, one can always find a Lévy-process $\hat{X}$ such that $\exp(X) = \mathcal{E}(\hat{X})$ and *vice versa* (in case the stochastic exponential is positive). The detailed calculations involving characteristic triplets can be found in Goll and Kallsen [3].

Finally, for any two semimartingales X, Y we have the formula

$$\mathcal{E}(X)\mathcal{E}(Y) = \mathcal{E}(X + Y + [X, Y]) \quad (7)$$

which generalizes the multiplicative property of the usual exponential function.

Martingale Property

The most crucial issue from the point of mathematical finance is that, given X is a local martingale, the stochastic exponential $\mathcal{E}(X)$ may fail to be a martingale. Let us give an illustration of this phenomenon.

We assume that the price process of a risky asset evolves as the stochastic exponential $Z_t = \exp(B_t - \frac{1}{2}t)$ where B is a standard Brownian motion starting in zero. Since one-dimensional Brownian motion is almost-surely recurrent, and therefore gets negative for arbitrarily large times, zero must be an accumulation point of Z . As Z can be written as a stochastic integral of B , it is a local martingale, and hence a supermartingale by Fatou's lemma

because it is bounded from below. We conclude by the supermartingale convergence theorem that Z converges (necessarily to zero). This shows that

$$\lim_{t \rightarrow \infty} Z_t = 0 \quad P - \text{a.s.} \quad (8)$$

Holding one stock of the asset with price process Z therefore amounts to following a suicide strategy, since one starts with an initial capital of one and ends up with no money at all at time infinity. The mathematical explanation for this phenomenon is that Z is not a martingale on the closed interval $[0, \infty]$, or equivalently, the family $\{Z_t, t \in \mathbb{R}_+\}$ is not uniformly integrable.

What is more, one of the main applications of stochastic exponentials is that they are intricately related to measure changes since they qualify as candidates for density processes (see Girsanov's theorem). Let us fix a filtered probability space $(\Omega, \mathcal{F}_\infty, (\mathcal{F}_t), P)$. In case the stochastic exponential is positive, we may define a new measure Q on $\mathcal{F}_\infty$ via

$$\frac{dQ}{dP} = Z_\infty \quad (9)$$

If Z is a uniformly integrable martingale, then Q is a probability measure since $E[Z_\infty] = Z_0 = 1$. On the other hand, if Z is a strict local martingale, hence a strict supermartingale, then we get $Q(\Omega) = E[Z_\infty] < 1$. It is therefore of paramount interest to have criteria at hand for stochastic exponentials to be true martingales. We first focus on the continuous case.

Theorem 1 (Kazamaki's Criterion). *Let M be a continuous local martingale. Suppose*

$$\sup_T E \left[\exp \left(\frac{1}{2} M_T \right) \right] < \infty \quad (10)$$

where the supremum is taken over all bounded stopping times T . Then $\mathcal{E}(M)$ is a uniformly integrable martingale.

A slightly weaker result, which, however, is often easier to apply, is given by the following criterion.

Theorem 2 (Novikov's Criterion). *Let M be a continuous local martingale. Suppose*

$$E \left[\exp \left(\frac{1}{2} [M]_\infty \right) \right] < \infty \quad (11)$$

Then $\mathcal{E}(M)$ is a uniformly integrable martingale.

Nevertheless, these results are still not applicable in many practically important situations, for example, if one wants to construct martingale measures in stochastic volatility models driven by Brownian motions. In that case, the following result taken from Liptser and Shiryaev [8] often turns out to be useful.

Theorem 3 *Let T be a finite time horizon, ϑ a predictable process with*

$$P \left(\int_0^T \vartheta_s^2 ds < \infty \right) = 1 \quad (12)$$

and B a Brownian motion. Provided that there is $\varepsilon > 0$ such that

$$\sup_{0 \leq t \leq T} E \left[\exp \left(\varepsilon \vartheta_t^2 \right) \right] < \infty \quad P - \text{a.s.} \quad (13)$$

then the stochastic exponential $\mathcal{E}(\int \vartheta dB)$ is a martingale on $[0, T]$.

Let us now turn to the discontinuous case. A generalization of Novikov's criterion has been obtained by Lepingle and Mémín [7] where more results in this direction can be found.

Theorem 4 *Let M be a locally bounded local P -martingale with $\Delta M > -1$. If*

$$E \left[\exp \left(\frac{1}{2} [M^c]_\infty \right) \prod_t (1 + \Delta M_t) \times \exp \left(-\frac{\Delta M_t}{1 + \Delta M_t} \right) \right] < \infty \quad (14)$$

then $\mathcal{E}(M)$ is a uniformly integrable martingale. Here M^c denotes the continuous local martingale part of M .

The situation is particularly transparent for Lévy processes; see Cont and Tankov [1].

Theorem 5 *If M is both a Lévy process and a local martingale, then its stochastic exponential $\mathcal{E}(M)$ (given that it is positive) is already a martingale.*

Alternative conditions for ensuring that stochastic exponentials are martingales in case of Brownian motion driven stochastic volatility models have been

provided in Hobson [4] as well as in Wong and Heyde [9]. Moreover, Kallsen and Shiryaev [6] give results generalizing and complementing the criterions in Lepingle and Mémin [7]. In case of local martingales of stochastic exponential form $\mathcal{E}(X)$, where X denotes one component of a multivariate affine process, Kallsen and Muhle-Garbe [5] give sufficient conditions for M to be a true martingale. Finally, there are important links between stochastic exponentials of BMO -martingales, reverse Hölder inequalities, and weighted norm inequalities (i.e., inequalities generalizing martingale inequalities to certain semimartingales); compare Doléans-Dade and Meyer [2].

THORSTEN RHEINLÄNDER

Martingales

The word *martingale* originated from Middle French. It means a device for steadying a horse's head or checking its upward movement. In eighteenth-century France, *martingale* also referred to a class of betting strategies in which a player increases the stake usually by doubling each time a bet is lost. The word "martingale", which appeared in the official dictionary of the Academy in 1762 (in the sense of a strategy) means "a strategy that consists in betting all that you have lost". See [7] for more about the origin of martingales. The simplest version of the *martingale betting strategies* was designed to beat a fair game in which the gambler wins his stake if a coin comes up heads and loses it if the coin comes up tails. The strategy had the gambler keep doubling his bet until the first head eventually occurs. At this point, the gambler stops the game and recovers all previous losses, besides winning a profit equal to the original stake. Logically, if a gambler is able to follow this "doubling strategy" (in French, it is still referred to as *la martingale*), he would win sooner or later. But in reality, the exponential growth of the bets would bankrupt the gambler quickly. It is Doob's optional stopping theorem (the cornerstone of martingale theory) that shows the impossibility of successful betting strategies.

In probability theory, a *martingale* is a stochastic process (a collection of random variables) such that the conditional expectation of an observation at some future time t , given all the observations up to some earlier time $s < t$, is equal to the observation at that earlier time s . The name "martingale" was introduced by Jean Ville (1910–1989) as a synonym of "gambling system" in his book on "collectif" in the Borel collection, 1938. However, the concept of martingale was created and investigated as early as in 1934 by Paul Pierre Lévy (1886–1971), and a lot of the original development of the theory was done by Joseph Leo Doob (1910–2004). At present, the martingale theory is one of the central themes of modern probability. It plays a very important role in the study of stochastic processes. In practice, a martingale is a model of a fair game. In financial markets, a fair game means that there is no arbitrage. Mathematical finance builds the bridge that connects no-arbitrage arguments and martingale theory. The fundamental theorem (principle) of asset pricing states, roughly

speaking, that a mathematical model for stochastic asset prices X is free of arbitrage if and only if X is a martingale under an equivalent probability measure. The fair price of a *contingent claim* associated with those assets X is the expectation of its payoff under the martingale equivalent measure (risk neutral measure).

Martingale theory is a vast field of study, and this article only gives an introduction to the theory and describes its use in finance. For a complete description, readers should consult texts such as [4, 13] and [6].

Discrete-time Martingales

A (finite or infinite) sequence of random variables $X = \{X_n | n = 0, 1, 2, \dots\}$ on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ is called a discrete-time *martingale* (respectively, *submartingale*, *supermartingale*) if for all $n = 0, 1, 2, \dots$, $\mathbb{E}[X_n] < \infty$ and

$$\mathbb{E}[X_{n+1} | X_0, X_1, \dots, X_n] = X_n$$

(respectively $\geq X_n$, $\leq X_n$) (1)

By the tower property of conditional expectations, equation (1) is equivalent to

$$\mathbb{E}[X_n | X_0, X_1, \dots, X_k] = X_k$$

(respectively $\geq X_k$, $\leq X_k$), for any $k \leq n$ (2)

Obviously, X is a submartingale if and only if $-X$ is a supermartingale. Every martingale is also a submartingale and a supermartingale; conversely, any stochastic process that is both a submartingale and a supermartingale is a martingale. The expectation $\mathbb{E}[X_n]$ of a martingale X at time n , is a constant for all n . This is one of the reasons that in a fair game, the asset of a player is supposed to be a martingale. For a supermartingale X , $\mathbb{E}[X_n]$ is a nonincreasing function of n , whereas for a submartingale X , $\mathbb{E}[X_n]$ is a nondecreasing function of n . Here is a mnemonic for remembering which is which: "*Life is a supermartingale; as time advances, expectation decreases.*" The conditional expectation of X_n in equation (2) should be evaluated on the basis

of *all* information available up to time k , which can be summarized by a σ -algebra $\mathcal{F}_k$,

$$\mathcal{F}_k = \{\text{all events occurring at times } i = 0, 1, 2, \dots, k\} \quad (3)$$

A sequence of increasing σ -algebras $\{\mathcal{F}_n | n = 0, 1, 2, \dots\}$, that is, $\mathcal{F}_k \subseteq \mathcal{F}_n \subseteq \mathcal{F}$ for $k \leq n$, is called a *filtration*, denoted by $\mathbb{F}$. When $\mathcal{F}_n$ is the smallest σ -algebra containing all the information of X up to time n , $\mathcal{F}_n$ is called the σ -algebra generated by $X_0, X_1, \dots, X_n$, denoted by $\sigma\{X_0, X_1, \dots, X_n\}$, and $\mathbb{F}$ is called the *natural filtration* of X . For another sequence of random variables $\{Y_k | k = 0, 1, \dots\}$, let $\mathcal{F}_k = \sigma\{Y_0, Y_1, \dots, Y_k\}$, then $\mathbb{E}[X_n | Y_0, Y_1, \dots, Y_k] = \mathbb{E}[X_n | \mathcal{F}_k]$.

A sequence of random variables $X = \{X_n | n = 0, 1, 2, \dots\}$ on the filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ is said to be *adapted* if X_n is $\mathcal{F}_n$ -measurable for each n , which means that given $\mathcal{F}_n$, there is no randomness in X_n . An adapted X is called a discrete-time *martingale* (respectively *submartingale*, *supermartingale*) with respect to the filtration $\mathbb{F}$, if for each n , $\mathbb{E}[|X_n|] < \infty$, and

$$\mathbb{E}[X_n | \mathcal{F}_k] = X_k \quad (\text{respectively } \geq X_k, \leq X_k), \quad \text{for any } k \leq n \quad (4)$$

Example 1 (Closed Martingales). Let Z be a random variable with $\mathbb{E}[Z] < \infty$, then for any filtration $\mathbb{F} = (\mathcal{F}_n)$, $X_n = \mathbb{E}[Z | \mathcal{F}_n]$ is a martingale (also called a *martingale closed by Z*). Conversely, for any martingale X on a finite probability space, there exists a random variable Z such that $X_n = \mathbb{E}[Z | \mathcal{F}_n]$.

Example 2 (Partial Sums of i.i.d. Random Variables). Let $Z_1, Z_2, \dots$ be a sequence of independent, identically distributed (i.i.d.) random variables such that $\mathbb{E}[Z_n] = \mu$, and $\mathbb{E}[Z_n^2] = \sigma^2 < \infty$, and that the moment generating function $\phi(\theta) = \mathbb{E}[e^{\theta Z_1}]$ exists for some $\theta > 0$. Let S_n be the partial sum, $S_n = Z_1 + \dots + Z_n$, also called a *random walk*. Let $\mathcal{F}_n = \sigma\{Z_1, \dots, Z_n\}$. Then

$$S_n - n\mu, \quad (S_n - n\mu)^2 - n\sigma^2, \quad \frac{\theta^{S_n}}{[\phi(\theta)]^n} \quad (5)$$

are all martingales. If $\mathbb{P}(Z_k = +1) = p$, $\mathbb{P}(Z_k = -1) = q = 1 - p$, then S_n is called a *simple random*

walk and $(q/p)^{S_n}$ is a martingale since $\phi(p/q) = 1$; in particular, when $p = q = 1/2$, S_n is called a *simple symmetric random walk*. If Z_k has the Bernoulli distribution, $\mathbb{P}(Z_k = +1) = p$, $\mathbb{P}(Z_k = 0) = q = 1 - p$, then S_n has the binomial distribution (n, p) , and $(q/p)^{2S_n - n}$ is a martingale since $\phi([q/p]^2) = q/p$.

Example 3 (Polya's Urn). An urn initially contains r red and b blue marbles. One is chosen randomly. Then it is put back together with another one of the same color. Let X_n be the number of red marbles in the urn after n iterations of this procedure, and let $Y_n = X_n/(n + r + b)$. Then the sequence Y_n is a martingale.

Example 4 (A Convex Function of Martingales). By Jensen's inequality, a convex function of a martingale is a submartingale. Similarly, a convex and nondecreasing function of a submartingale is also submartingale. Examples of convex functions are $\max(x - k, 0)$ for constant k , $|x|^p$ for $p \geq 1$ and $e^{\theta x}$ for constant θ .

Example 5 (Martingale Transforms). Let X be a martingale with respect to the filtration $\mathbb{F}$ and H be a *predictable process* with respect to $\mathbb{F}$, that is, H_n is $\mathcal{F}_{n-1}$ -measurable for $n \geq 1$, where $\mathcal{F}_0 = \{\emptyset, \Omega\}$. A martingale transform of X by H is defined by

$$(H \cdot X)_n = H_0 X_0 + \sum_{i=1}^n H_i (X_i - X_{i-1}) \quad (6)$$

where the expression $H \cdot X$ is the discrete analog of the *stochastic integral* $\int H dX$. If $\mathbb{E}|(H \cdot X)_n| < \infty$ for $n \geq 1$, then $(H \cdot X)_n$ is a martingale with respect to $\mathbb{F}$. The interpretation is that in a fair game X , if we choose our bet at each stage on the basis of the prior history, that is, the bet H_n for the n th gamble only depends on $\{X_0, X_1, \dots, X_{n-1}\}$, then the game will continue to be fair. If X_n is the asset price at time n and H_n is the number of shares of the assets held by the investor during the time period from time n until time $n + 1$, more precisely, for the time interval $[n, n + 1)$, then $(H \cdot X)_n$ is the total gain (or loss) up to time n (the value of the portfolio at time n with the trading strategy H).

A random variable T taking values in $\{0, 1, 2, \dots, \infty\}$ is a *stopping time* T with respect to a filtration $\mathbb{F} = \{\mathcal{F}_n | n = 0, 1, 2, \dots\}$, if for each n , the

event $\{T = n\}$ is $\mathcal{F}_n$ -measurable, or equivalently, the event $\{T \leq n\}$ is $\mathcal{F}_n$ -measurable. If S and T are stopping times, then $S + T$, $S \vee T = \max(S, T)$, and $S \wedge T = \min(S, T)$ are all stopping times. Particularly, $T \wedge n$ is a bounded stopping time for any fixed time n . $X_n^T =: X_{T \wedge n}$ is said to be the *process X stopped at T* , since on the event $\{\omega | T(\omega) = k\}$, $X_n^T = X_k$ for $n = k, k + 1, \dots$.

Doob's Optional Stopping Theorem

Let X be a martingale and T be a bounded stopping time with respect to the same filtration $\mathbb{F}$, then $\mathbb{E}[X_T] = \mathbb{E}[X_0]$. Conversely, for an adapted process X , if $\mathbb{E}[|X_T|] < \infty$ and $\mathbb{E}[X_T] = \mathbb{E}[X_0]$ hold for all bounded stopping time T , then X is a martingale. This theorem says roughly that stopping a martingale at a stopping time T does not alter its expectation, provided that the decision when to stop is based only on information available up to time T . The theorem also shows that a martingale stopped at a stopping time is still a martingale, and there is no way to be sure to win in a fair game if the stopping time is bounded.

Continuous-time Martingales

A continuous-time stochastic process X on filtered probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$ is a collection of random variables $X = \{X_t : 0 \leq t \leq \infty\}$, where X_t is a random variable observed at time t , and the filtration $\mathbb{F} = \{\mathcal{F}_t : 0 \leq t \leq \infty\}$, which is a family of increasing σ -algebras, $\mathcal{F}_s \subseteq \mathcal{F}_t \subseteq \mathcal{F}$ for $s \leq t$. A process X is said to be *adapted* if X_t is $\mathcal{F}_t$ measurable for each t . A random variable T taking values in $[0, \infty]$ is called a *stopping time*, if the event $\{T \leq t\}$ is $\mathcal{F}_t$ measurable for each t . The *stopping time σ -algebra $\mathcal{F}_T$* is defined to be $\mathcal{F}_T = \{A \in \mathcal{F} | A \cap \{T \leq t\} \in \mathcal{F}_t, \text{ all } t \geq 0\}$, which represents the information up to the stopping time T .

A real-valued, adapted process X is called a continuous-time *martingale* (respectively *supermartingale*, *submartingale*) with respect to the filtration $\mathbb{F}$ if

$$1. \quad \mathbb{E}[|X_t|] < \infty, \quad \text{for } t > 0 \quad (7)$$

$$2. \quad \mathbb{E}[X_t | \mathcal{F}_s] = X_s \text{ (respectively } \leq X_s, \geq X_s), \\ \text{a.s. for any } 0 \leq s \leq t \quad (8)$$

Continuous-time martingales have the same properties as discrete-time martingales. For example, *Doob's optional stopping theorem* says that for a martingale X_t with right continuous paths, which is closed in $\mathbf{L}^1$ by a random variable X_∞ , we have

$$\mathbb{E}[X_T | \mathcal{F}_S] = X_S \quad \text{a.s. for any two stopping times} \\ 0 \leq S \leq T \quad (9)$$

The most important continuous-time martingale is Brownian motion, which was named for the Scottish botanist Robert Brown, who, in 1827, observed ceaseless and irregular movement of pollen grains suspended in water. It was studied by Albert Einstein in 1905 at the level of modern physics. Its mathematical model was first rigorously constructed in 1923 by Norbert Wiener. Brownian motion is also called a *Wiener process*. The Wiener process gave rise to the study of continuous-time martingales, and has been an example that helps mathematicians to understand stochastic calculus and diffusion processes.

It was Louis Bachelier (1870–1946), now recognized as the founder of mathematical finance (see [9]), who first, in 1900, used Brownian motion B to model short-term stock prices S_t at a time t in financial markets, that is, $S_t = S_0 + \sigma B_t$, where $\sigma > 0$ is a constant. Now we can see that if Brownian motion B is defined on $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$, then the price process S is a martingale under the probability measure $\mathbb{P}$.

In 1965, the American economist Paul Samuelson rediscovered Bachelier's ideas and proposed the *geometric Brownian motion* $S_0 \exp\{(\mu - (\sigma^2/2))t + \sigma B_t\}$ as a model for long-term stock prices S_t . That is, S_t follows the stochastic differential equation (SDE): $dS_t = \mu S_t dt + \sigma S_t dB_t$. From this simple structure, we get the famous Black–Scholes option price formulas for European calls and puts. This SDE is now called the Black–Scholes equation (model). Contrary to Bachelier's setting, the price process S is not a martingale under $\mathbb{P}$. However, by Girsanov's theorem, there is a unique probability measure $\mathbb{Q}$, which is equivalent to $\mathbb{P}$, such that the discounted stock price $e^{-rt} S_t$ is a martingale under $\mathbb{Q}$ for $0 \leq t \leq T$, where r is the *riskless rate of interest*, and $T > 0$ is a fixed constant.

The reality is not as simple as the above linear SDE. A simple generalization is $dS_t = \mu(t, S_t) dt + \sigma(t, S_t) dB_t$. If one believes that risky asset prices

have jumps, an appropriate model might be

$$dS_t = \mu(t, S_t) dt + \sigma(t, S_t) dB_t + J(t, S_t) dN_t \quad (10)$$

where N is a Poisson process with intensity λ , $J(t, S_t)$ refers to the jump size, and N indicates when the jumps occur. Since N is a counting (pure jump) process with independent and stationary increments, both $N_t - \lambda t$ and $(N_t - \lambda t)^2 - \lambda t$ are martingales. For a more general model, we could replace N by a Lévy process that includes the Brownian motion and Poisson process as special cases.

Under these general mathematical models, it becomes hard to turn the fundamental principle of asset pricing into a precise mathematical theorem: the absence of arbitrage possibilities for a stochastic process S , a *semimartingale* defined on $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$, is equivalent to the existence of an equivalent measure $\mathbb{Q}$, under which S is a *local martingale*, sometimes, a *sigma martingale*. See [2] or [3].

Local Martingales and Finite Variation Processes

There are two types of processes with only jump discontinuities. A process is said to be *càdlàg* if it almost surely (a.s.) has sample paths that are right continuous, with left limits. A process is said to be *càglàd* if it almost surely has sample paths that are left continuous, with right limits. The words *càdlàg* and *càglàd* are acronyms from the French for *continu à droite, limites à gauche*, and *continu à gauche, limites à droite*, respectively. Let

$$\begin{aligned} \mathbb{D} &= \text{the space of adapted processes} \\ &\quad \text{with càdlàg paths} \\ \mathbb{L} &= \text{the space of adapted processes} \\ &\quad \text{with càglàd paths} \end{aligned} \quad (11)$$

An adapted, càdlàg process A is called a *finite variation* (FV) process if $\sup \sum_{i=1}^N |A_{t_i} - A_{t_{i-1}}|$ is bounded almost surely for each constant $t > 0$, where the supremum is taken over the set of all partitions $0 = t_0 \leq t_1 \leq \dots \leq t_N = t$. An FV process is a difference of two increasing processes. Although the Brownian motion B has continuous paths, it has

paths of *infinite variation* on $[0, t]$, which prevents us from defining the stochastic integral $\int H dB$ as a *Riemann–Stieltjes integral*, path by path.

An adapted, càdlàg process M is called a *local martingale* with respect to a filtration $\mathbb{F}$ if there exists a sequence of increasing stopping time T_n with $\lim_{n \rightarrow \infty} T_n = \infty$ almost surely, such that for each n , $M_{t \wedge T_n}$ is a martingale. A similar concept is that a function is *locally bounded*: for example, $1/t$ is not bounded over $(0, 1]$, but it is bounded on the interval $[1/n, 1]$ for any integer n . A process moving very rapidly though with continuous paths, or jumping unboundedly and frequently, might not be a martingale. However, we could modify it to be a martingale by stopping it properly, that is, it is a martingale up to a stopping time, but may not be a martingale for all time.

The class of local martingales includes martingales as special cases. For example, if for every $t > 0$, $\mathbb{E}\{\sup_{s \leq t} |M_s|\} < \infty$, then M is a martingale; if for all $t > 0$, $\mathbb{E}\{[M, M]_t\} < \infty$, then M is a martingale, and $\mathbb{E}\{M_t^2\} = \mathbb{E}\{[M, M]_t\}$. Conversely, if M is a martingale with $\mathbb{E}\{M_t^2\} < \infty$ for all $t > 0$, then $\mathbb{E}\{[M, M]_t\} < \infty$ for all $t > 0$. For the definition of quadratic variation $[M, M]_t$, see equation (14) in the next section.

Not all local martingales are martingales. Here is a typical *example* of a local martingale, but not a martingale. Lots of continuous-time martingales, supermartingales, and submartingales can be constructed from Brownian motion, since it has independent and stationary increments and it can be approximated by a random walk. For example, let B be a standard Brownian motion in $\mathbb{R}^3$ with $B_0 = x \neq 0$. Let $u(y) = \|y\|^{-1}$, be a *superharmonic* function on $\mathbb{R}^3$. $M_t = u(B_t)$ is a positive supermartingale. Since $\lim_{t \rightarrow \infty} \sqrt{t} \mathbb{E}\{M_t\} = \sqrt{\pi}$ and $\mathbb{E}\{M_0\} = u(x)$, M does not have constant expectations and it cannot be a martingale. M is known as the *inverse Bessel Process*. For each n , we define a stopping time $T_n = \inf\{t > 0 : \|B_t\| \leq 1/n\}$. Since the function u is *harmonic* outside of the ball of radius $1/n$ centered at the origin, the process $\{M_{t \wedge T_n} : t \geq 0\}$ is a martingale for each n . Therefore, M is a local martingale.

Semimartingales and Stochastic Integrals

Today stocks and bonds are traded globally almost 24 hours a day, and online trading happens every second.

When trading takes place almost continuously, it is simpler to use a continuous-time stochastic processes to model the price X . The value of the portfolio at time t with the continuous-time trading strategy H becomes the limit of sums as shown in the martingale transform $(H \cdot X)_n$ in equation (6), that is, the stochastic integral $\int_0^t H_s dX_s$. Stochastic calculus is more complicated than regular calculus because X can have paths of infinite variation, especially when X has unbounded jumps, for example, when X is Brownian motion, a continuous-time martingale, or a local martingale. For stochastic integration theory, see **Stochastic Integrals** or consult [8, 11] and [12], and other texts.

Let $0 = T_1 \leq \dots \leq T_{n+1} < \infty$ be a sequence of stopping times and $H_i \in \mathcal{F}_{T_i}$ with $|H_i| < \infty$. A process H with a representation

$$H_t = H_0 \mathbf{1}_{\{0\}}(t) + \sum_{i=1}^n H_i \mathbf{1}_{(T_i, T_{i+1}]}(t) \quad (12)$$

is called a *simple predictable process*. A collection of simple predictable processes is denoted by $\mathbf{S}$. For a process $X \in \mathbb{D}$ and $H \in \mathbf{S}$ having the representation (12), we define a linear mapping as the martingale transforms in equation (6) in the discrete-time case

$$(H \cdot X)_t = H_0 X_0 + \sum_{i=1}^n H_i (X_{t \wedge T_{i+1}} - X_{t \wedge T_i}) \quad (13)$$

If for any $H \in \mathbf{S}$ and each $t \geq 0$, the sequence of random variables $(H^n \cdot X)_t$ converges to $(H \cdot X)_t$ in probability, whenever $H^n \in \mathbf{S}$ converges to H uniformly, then X is called a *semimartingale*. For example, an FV process, a local martingale with continuous paths, and a Lévy process are all semimartingales.

Since the space $\mathbf{S}$ is dense in $\mathbb{L}$, for any $H \in \mathbb{L}$, there exists $H_n \in \mathbf{S}$ such that H_n converges to H . For a semimartingale X and a process $H \in \mathbb{L}$, the *stochastic integral* $\int H dX$, also denoted by $(H \cdot X)$, is defined by $\lim_{n \rightarrow \infty} (H^n \cdot X)$. For any $H \in \mathbb{L}$, $H \cdot X$ is a semimartingale, it is an FV process if X is, and it is a local martingale if X is. But $H \cdot X$ may not be a martingale even if X is. $H \cdot X$ is a martingale if X is a local martingale and $\mathbb{E}\{\int_0^t H_s^2 d[X, X]_s\} < \infty$ for each $t > 0$.

For a semimartingale X , its *quadratic variation* $[X, X]$ is defined by

$$[X, X]_t = X_t^2 - 2 \int_0^t X_{s-} dX_s \quad (14)$$

where X_{s-} denotes the left limit at s . Let $[X, X]^c$ denote the path-by-path continuous part of $[X, X]$, and $\Delta X_s = X_s - X_{s-}$ be the jump of X at s , then $[X, X]_t = [X, X]_t^c + \sum_{0 \leq s \leq t} (\Delta X_s)^2$. For an FV process X , $[X, X]_t = \sum_{0 \leq s \leq t} (\Delta X_s)^2$. In particular, if X is an FV process with continuous paths, then $[X, X]_t = X_0^2$ for all $t \geq 0$. For a continuous local martingale X , then $X^2 - [X, X]_t$ is a continuous local martingale. Moreover, if $[X, X]_t = X_0^2$ for all t , then $X_t = X_0$ for all t ; in other words, if an FV process is also a continuous local martingale, then it is a constant process.

Lévy's Characterization of Brownian Motion

A process X is a standard Brownian motion if and only if it is a continuous local martingale with $[X, X]_t = t$.

The theory of stochastic integration for integrands in $\mathbb{L}$ is sufficient to establish Itô's formula, the Girsanov–Meyer theorem, and to study SDEs. For example, the *stochastic exponential* of a semimartingale X with $X_0 = 0$, written $\mathcal{E}(X)$, is the unique semimartingale Z that is a solution of the linear SDE: $Z_t = 1 + \int_0^t Z_{s-} dX_s$. When X is a continuous local martingale, so is $\mathcal{E}(X)_t = \exp\{X_t - \frac{1}{2}[X, X]_t\}$. Furthermore, if *Kazamaki's Criterion* $\sup_T \mathbb{E}\{\exp(\frac{1}{2}X_T)\} < \infty$ holds, where the supremum is taken over all bounded stopping times, or if *Novikov's Criterion* $\mathbb{E}\{\exp(\frac{1}{2}[X, X]_\infty)\} < \infty$ holds (stronger but easier to check in practice), then $\mathcal{E}(X)$ is a martingale. See [10] for more on these conditions. When X is Brownian motion, $\mathcal{E}(X) = \exp\{X_t - \frac{1}{2}t\}$ is referred to as *geometric Brownian motion*.

The space of integrands $\mathbb{L}$ is not general enough to have *local times* and martingale representation theory, which is essential for hedging in finance. On the basis of the *Bichteler–Dellacherie theorem*, X is a semimartingale if and only if $X = M + A$, where M is a local martingale and A is an FV process, we can extend the stochastic integration from $\mathbb{L}$ to the space $\mathcal{P}$ of predictable processes, which are measurable with respect to $\sigma\{H : H \in \mathbb{L}\}$. For a semimartingale

X , if a predictable H is X integrable, that is, we can define the stochastic integral $H \cdot X$, then we write $H \in L(X)$ (see chapter 4 of [8]). If $H \in \mathcal{P}$ is locally bounded then $H \in L(X)$ and $H \cdot X$ is a local martingale if X is. However, if $H \in \mathcal{P}$ is not locally bounded or $H \notin \mathbb{L}$, then $H \cdot X$ may not be a local martingale even if X is an $\mathbf{L}^2$ martingale. For such an example due to M. Émery, see pp 152 of [5] or pp 176 of [8]. If X is a local martingale and $H \in L(X)$, then $H \cdot X$ is a sigma martingale.

Sigma Martingales

The concept of a sigma martingale was introduced by Chou [1] and further analyzed by Émery [5]. It has seen a revival in popularity owing to Delbaen and Schachermayer [2]; see [8] for a more detailed treatment. Sigma martingales relate to martingales analogously as sigma-finite measures relate to finite measures. A sigma martingale, which may not be a local martingale, has the essential features of a martingale.

A semimartingale X is called a *sigma martingale* if there exists a martingale M and a nonnegative $H \in \mathcal{P}$ such that $X = H \cdot M$, or, equivalently, if there exists a nonnegative $H \in \mathcal{P}$ such that $H \cdot X$ is a martingale.

A local martingale is a sigma martingale, but a sigma martingale with large jumps might fail to be a local martingale. If X is a sigma martingale and if either $\sup_{s \leq t} |X_s|$ or $\sup_{s \leq t} |\Delta X_s|$ is *locally integrable* (for example, X has continuous paths or bounded jumps), then X is a local martingale. If X is a sigma martingale and $H \in L(X)$, then $H \cdot X$ is always a sigma martingale.

The concept of a sigma martingale is new in the context of mathematical finance. It was introduced to deal with possibly unbounded jumps of the asset price process X . When we consider the process X with jumps, it is often convenient to assume the jumps to be unbounded, for example, the Lévy processes and the family of ARCH, GARCH processes. If the conditional distribution of jumps is Gaussian, then the process is not locally bounded. In that case, the concept of a sigma martingale is unavoidable. On the other hand, if we are only interested in how to price and hedge some contingent claims, not the underlying assets X , then it might not be necessary to require the asset price X to be a (local) martingale

and it suffices to require $H \cdot X$ to be a martingale for some H , that is, X is a sigma martingale. Moreover, nonnegative sigma martingales are local martingales, so in particular for stock prices, we do need to consider sigma martingales.

Finally, we cite two *fundamental theorems of asset pricing* from chapters 8 and 14 of [3] to see why we need sigma martingales in mathematical finance.

Theorem 1 *Let the discounted price process S be a locally bounded semimartingale defined on $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$. Then there exists a probability measure $\mathbb{Q}$ (equivalent to $\mathbb{P}$) under which S is a local martingale, if and only if S satisfies the condition of no free lunch with vanishing risk (NFLVR).*

Here the concept of NFLVR is a mild strengthening of the concept of no arbitrage, which is introduced by Delbaen and Schachermayer in [2].

Theorem 2 *If we assume that S is a nonlocally bounded semimartingale, then we have a general theorem by replacing the term “local martingale” by the term “sigma martingale” in Theorem 1 above. However if $S \geq 0$, then “local martingale” suffices, because sigma martingales bounded below are a priori local martingales.*

Conclusion

A local martingale is a martingale up to a sequence of stopping times that goes to ∞ , while a sigma martingale is a countable sum (a mixture) of martingales.

Itô's Formula

For a function depending on space and time parameters, rules of differentiation are well known. For a function depending on space and time parameters and also on a randomness parameter, Itô's formulas provide rules of differentiation. These rules of differentiation are based on the complementary notion of stochastic integration (see **Stochastic Integrals**). More precisely, given a probability space $(\Omega, \mathbb{P}, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0})$, Itô's formulas deal with $(F(X_t); t \geq 0)$, where F is a deterministic function defined on $\mathbb{R}$ and $(X_t)_{t \geq 0}$ is a random process such that integration of locally bounded predictable processes is possible with respect to $(X_t)_{t \geq 0}$ and satisfies a property equivalent to the Lebesgue dominated convergence theorem. This means that $(X_t)_{t \geq 0}$ is a semimartingale and therefore has a finite quadratic variation process $([X]_t, t \geq 0)$ (see **Stochastic Integrals**) defined as

$$[X]_t = \lim_{n \rightarrow \infty} \sum \left(X_{s_{i+1}^n} - X_{s_i^n} \right)^2 \text{ in probability,} \\ \text{uniformly on time intervals} \quad (1)$$

where $(s_i^n)_{1 \leq i \leq n}$ is a subdivision of $[0, t]$ whose mesh converges to 0 as n tends to ∞ .

We will see that Itô's formulas also provide information on the stochastic structure of the process $(F(X_t), t \geq 0)$. We first introduce the formula established by Itô in 1951. Consider a process $(X_t)_{t \geq 0}$ of the form

$$X_t = \int_0^t H_s dB_s + \int_0^t G_s ds \quad (2)$$

where $(B_s)_{s \geq 0}$ is a real-valued Brownian motion, and $(H_s)_{s \geq 0}$ and $(G_s)_{s \geq 0}$ are locally bounded predictable processes. Then for every C^2 -function F from $\mathbb{R}$ to $\mathbb{R}$, we have

$$F(X_t) = F(X_0) + \int_0^t F'(X_s) H_s dB_s \\ + \int_0^t F'(X_s) G_s ds + \frac{1}{2} \int_0^t H_s^2 F''(X_s) ds \quad (3)$$

The process defined in formula (2) is an example of continuous semimartingale. Here is the classical Itô formula for a general semimartingale $(X_s)_{s \geq 0}$ (e.g., [7, 9]) and F in $\mathcal{C}^2$

$$F(X_t) = F(X_0) + \int_0^t F'(X_{s-}) dX_s \\ + \frac{1}{2} \int_0^t F''(X_s) d[X]_s^c \\ + \sum_{0 \leq s \leq t} \left\{ F(X_s) - F(X_{s-}) - F'(X_{s-}) \Delta X_s \right\} \quad (4)$$

where $[X]^c$ is the continuous part of $[X]$. For continuous semimartingales, formula (4) becomes

$$F(X_t) = F(X_0) + \int_0^t F'(X_s) dX_s \\ + \frac{1}{2} \int_0^t F''(X_s) d[X]_s \quad (5)$$

In the special case when $(X_t)_{t \geq 0}$ is a real Brownian motion, then $[X]_t = t$.

The multidimensional version of formula (4) gives the expansion of $F(X_t^{(1)}, X_t^{(2)}, \dots, X_t^{(d)})$ for F a real-valued function of $\mathcal{C}^2(\mathbb{R}^d)$ and d semimartingales $X^{(1)}, X^{(2)}, \dots, X^{(d)}$. We set $X = (X^{(1)}, X^{(2)}, \dots, X^{(d)})$:

$$F(X_t) = F(X_0) + \sum_{i=1}^d \int_0^t \frac{\partial F}{\partial x_i}(X_{s-}) dX_s^{(i)} \\ + \frac{1}{2} \sum_{1 \leq i, j \leq d} \int_0^t \frac{\partial^2 F}{\partial x_i \partial x_j}(X_{s-}) d[X^{(i)}, X^{(j)}]_s^c \\ + \sum_{0 \leq s \leq t} \left\{ F(X_s) - F(X_{s-}) \right. \\ \left. - \sum_{i=1}^d \frac{\partial F}{\partial x_i}(X_{s-}) \Delta X_s^{(i)} \right\} \quad (6)$$

Note the Itô formula corresponding to the case of the couple of semimartingales $(X_t, t)_{t \geq 0}$ with X

continuous and F in $\mathcal{C}^2(\mathbb{R}^2)$

$$\begin{aligned} F(X_t, t) = & F(X_0, 0) + \int_0^t \frac{\partial F}{\partial x}(X_s, s) dX_s \\ & + \int_0^t \frac{\partial F}{\partial t}(X_s, s) ds \\ & + \frac{1}{2} \int_0^t \frac{\partial^2 F}{\partial x^2}(X_s, s) d[X]_s \end{aligned} \quad (7)$$

Each of the above Itô formulas gives a decomposition of the process $(F(X_t), t \geq 0)$ that can be reduced to the sum of a local martingale and an adapted bounded variation process. This shows that $F(X)$ is a semimartingale. In practical situations, the considered function F might not be a $\mathcal{C}^2$ -function and the process $F(X)$ might not be a semimartingale. Hence, many authors have written extensions of the above formulas enlightening this $\mathcal{C}^2$ -condition. Some of them use the notion of local times (see **Local Times**) whose definition can actually be set by the following first extension of the Itô formula.

For F real-valued convex function and X semimartingale, $F(X)$ is a semimartingale too and

$$F(X_t) = F(X_0) + \int_0^t F'(X_{s-}) dX_s + A_t \quad (8)$$

where F' is the left derivative of F and $(A_t, t \geq 0)$ is an adapted, right continuous increasing process such that $\Delta A_s = F(X_s) - F(X_{s-}) - F'(X_{s-})\Delta X_s$.

Choosing $F(x) = |x - a|$, one obtains the existence of an increasing process $(L_t^a, t \geq 0)$ such that

$$\begin{aligned} |X_t - a| = & |X_0 - a| + \int_0^t \operatorname{sgn}(X_{s-} - a) dX_s + L_t^a \\ & + \sum_{0 < s \leq t} \{|X_s - a| - |X_{s-} - a| \\ & - \operatorname{sgn}(X_{s-} - a)\Delta X_s\} \end{aligned} \quad (9)$$

The process L^a is called the *local time process* of X at a (see **Local Times** for alternative definition and basic properties). Note that L^a is continuous in t .

Coming back to formula (8), denote by μ the second derivative of F in the generalized function sense; then the Meyer–Itô formula goes further by giving the expression of the bounded variation

process A :

$$\begin{aligned} F(X_t) = & F(X_0) + \int_0^t F'(X_{s-}) dX_s \\ & + \sum_{0 < s \leq t} \{F(X_s) - F(X_{s-}) - F'(X_{s-})\Delta X_s\} \\ & + \frac{1}{2} \int_{\mathbb{R}} L_t^x \mu(dx) \end{aligned} \quad (10)$$

The Meyer–Itô formula is also obviously available for functions F , which are difference of two convex functions.

For the semimartingales X , such that for every $t > 0$: $\sum_{0 < s \leq t} |\Delta X_s| < \infty$ a.s., Bouleau and Yor extended the Meyer–Itô formula to functions F , admitting a Radon–Nikodym derivative with respect to the Lebesgue measure. Indeed, the Bouleau–Yor formula [2] states in that case

$$\begin{aligned} F(X_t) = & F(X_0) + \int_0^t F'(X_{s-}) dX_s \\ & + \sum_{0 < s \leq t} \{F(X_s) - F(X_{s-}) - F'(X_{s-})\Delta X_s\} \\ & - \frac{1}{2} \int_{\mathbb{R}} F'(x) d_x L_t^x \end{aligned} \quad (11)$$

Note that the Bouleau–Yor formula requires the construction of a stochastic integration of deterministic functions with respect to the process $(L_t^x, x \in \mathbb{R})$, although this last process might not be a semimartingale. Besides, this formula shows that the process $(F(X_t), t \geq 0)$ might not be a semimartingale but a Dirichlet process (i.e., the sum of a local martingale and a 0-quadratic variation process).

In the special case of a real Brownian motion $(B_t, t \geq 0)$, Föllmer, Protter, and Shirayev formula offers an extension of the Bouleau–Yor formula to space–time functions G defined on $\mathbb{R} \times \mathbb{R}_+$ admitting a Radon–Nikodym derivative with respect to the space parameter $\partial G / \partial x$ with some continuity properties (see [6], for the detailed assumptions)

$$\begin{aligned} G(B_t, t) = & G(B_0, 0) + \int_0^t G(B_s, ds) \\ & + \int_0^t \frac{\partial G}{\partial x}(B_s, s) dB_s + \frac{1}{2} \left[\frac{\partial G}{\partial x}(B, \cdot, \cdot), B \right]_t \end{aligned} \quad (12)$$

with $\int_0^t G(B_s, ds) = \lim_{n \rightarrow \infty} \sum_{i=1}^n (G(B_{s_{i+1}^n}, s_{i+1}^n) - G(B_{s_i^n}, s_i^n))$ in probability, where $(s_i^n)_{1 \leq i \leq n}$ is a subdivision of $[0, t]$ whose mesh converges to 0 as n tends to ∞ (Reference 5 contains a similar result and Reference 1 extends it to nondegenerate diffusions).

Another way to extend the Bouleau–Yor formula, in the case of a real Brownian motion, consists in the construction of the stochastic integration of locally bounded deterministic space–time functions $f(x, t)$ with respect to the local time process $(L_t^x, x \in \mathbb{R}, t \geq 0)$ of B . That way one obtains, for the functions G admitting locally bounded first-order derivatives, Eisenbaum's formula [3]:

$$\begin{aligned} G(B_t, t) &= G(B_0, 0) + \int_0^t \frac{\partial G}{\partial x}(B_s, s) dB_s \\ &\quad + \int_0^t \frac{\partial G}{\partial t}(B_s, s) ds \\ &\quad - \frac{1}{2} \int_0^t \int_{\mathbb{R}} \frac{\partial G}{\partial x}(x, s) dL_s^x \end{aligned} \quad (13)$$

The comparison of formula (13) with formulas (12) and (7) provides some rules of integration with respect to the local time process of B such as

- for f continuous function on $\mathbb{R} \times \mathbb{R}_+$

$$\int_0^t \int_{\mathbb{R}} f(x, s) dL_s^x = -[f(B, \cdot), B]_t \quad (14)$$

- for f locally bounded function on $\mathbb{R} \times \mathbb{R}_+$ admitting a locally bounded Radon–Nikodym derivative $\partial f / \partial x$

$$\int_0^t \int_{\mathbb{R}} f(x, s) dL_s^x = - \int_0^t \frac{\partial f}{\partial x}(X_s, s) ds \quad (15)$$

See [2] for an extension of formula (13) to Lévy processes.

We now mention the special case of a space–time function $G(x, s)$ defined as follows:

$$G(x, s) = G_1(x, s)1_{\{x > b(s)\}} + G_2(x, s)1_{\{x \leq b(s)\}} \quad (16)$$

where $(b(s), s \geq 0)$ is a continuous curve and G_1 and G_2 are $\mathcal{C}^2$ -functions that coincide on $x = b(s)$

(but not their derivatives). This case is treated in [8] for X continuous semimartingale and in [4] for X Lévy process such that $\sum_{0 \leq s \leq t} |\Delta X_s| < \infty$ a.s. Both use the notion of local time of X along the curve b denoted $(L_s^{b(\cdot)}, s \geq 0)$, defined as

$$L_t^{b(\cdot)} = \lim_{\epsilon \rightarrow 0} \frac{1}{2\epsilon} \int_0^t 1_{(|X_s - b(s)| < \epsilon)} d[X]_s^c$$

uniformly on compacts in L^1 (17)

When b is equal to the constant a , $L^{b(\cdot)}$ coincides with the local time at the value a . These formulas have the following form:

$$\begin{aligned} G(X_t, t) &= G(X_0, 0) + \int_0^t \frac{\partial G}{\partial x}(X_{s-}, s) dX_s \\ &\quad + \int_0^t \frac{\partial G_1}{\partial t}(X_s, s) 1_{(X_s < b(s))} ds \\ &\quad + \int_0^t \frac{\partial G_2}{\partial t}(X_s, s) 1_{(X_s \geq b(s))} ds \\ &\quad + \frac{1}{2} \int_0^t \left(\frac{\partial^2 G_1}{\partial x^2}(X_s, s) 1_{(x < b(s))} \right. \\ &\quad \left. + \frac{\partial^2 G_2}{\partial x^2}(X_s, s) 1_{(x \geq b(s))} \right) d[X]_s^c \\ &\quad + \frac{1}{2} \int_0^t \left(\frac{\partial G_2}{\partial x} - \frac{\partial G_1}{\partial x} \right) (b(s), s) d_s L_s^{b(\cdot)} \\ &\quad + \sum_{0 < s \leq t} \left\{ G(X_s, s) - G(X_{s-}, s) \right. \\ &\quad \left. - \frac{\partial G}{\partial x}(X_{s-}, s) \Delta X_s \right\} \end{aligned} \quad (18)$$

Note that $\partial G / \partial x$ exists as a Radon–Nikodym derivative and is equal to $(\partial G_1 / \partial x)(x, s) 1_{(x < b(s))} + (\partial G_2 / \partial x)(x, s) 1_{(x \geq b(s))}$. The formula (18) is helpful in free-boundary problems of optimal stopping. Other illustrations of formula (13) are given in [4] for multidimensional Lévy processes.

Lévy Copulas

Lévy copulas characterize the dependence among components of multidimensional Lévy processes. They are similar to copulas of probability distributions but are defined at the level of Lévy measures. Lévy copulas separate the dependence structure of a Lévy measure from the one-dimensional marginal measures meaning that any d -dimensional Lévy measure can be constructed from a set of one-dimensional margins and a Lévy copula. This suggests the construction of parametric multidimensional Lévy models by combining arbitrary one-dimensional Lévy processes with a Lévy copula from a parametric family. The Lévy copulas were introduced in [4] for spectrally one-sided Lévy processes and in [6, 7] in the general case. Subsequent theoretical developments include Barndorff-Nielsen and Lindner [1], who discuss further interpretations of Lévy copulas and various transformations of these objects. Farkas *et al.* [5] develop deterministic numerical methods for option pricing in models based on Lévy copulas, and the simulation algorithms for multidimensional Lévy processes based on their Lévy copulas are discussed in [4, 7].

In finance, Lévy copulas are useful to model joint moves of several assets in various settings including portfolio risk management, option pricing [8], insurance [3], and operational risk modeling [2].

Lévy Measures and Tail Integrals

A Lévy process on $\mathbb{R}^d$ is described by its characteristic triplet (A, ν, γ) , where A is a positive semidefinite $d \times d$ matrix, $\gamma \in \mathbb{R}^d$, and ν is a positive Radon measure on $\mathbb{R}^d \setminus \{0\}$, satisfying $\int_{\mathbb{R}^d \setminus \{0\}} (\|x\|^2 \wedge 1) \nu(dx) < \infty$ and called the *Lévy measure of X* . The matrix A is the covariance matrix of the continuous martingale (Brownian motion) part of X , and ν describes the independent jump part. It makes sense, therefore, to describe the dependence structure of the jump part of X with a suitable notion of copula at the level of the Lévy measure.

In the same way that the distribution of a random vector can be represented by its distribution function, the Lévy measure of a Lévy process will be represented by its tail integral. If we are only interested in,

say, positive jumps, the definition of the tail integral is simple: given a $\mathbb{R}^d$ -valued Lévy process with Lévy measure ν supported by $[0, \infty)^d$, the tail integral of ν is the function $U : (0, \infty)^d \rightarrow [0, \infty)$ defined by

$$U(x_1, \dots, x_d) = \nu((x_1, \infty) \times \dots \times (x_d, \infty)) \quad (1)$$

In the general case, care must be taken to avoid the possible singularity of ν near zero: so the tail integral is a function $U : (\mathbb{R} \setminus \{0\})^d \rightarrow \mathbb{R}$ defined by

$$U(x_1, \dots, x_d) := \prod_{i=1}^d \text{sgn}(x_i) \nu \left(\prod_{j=1}^d \mathcal{I}(x_j) \right) \quad (2)$$

where $\mathcal{I} := (x, \infty)$ if $x > 0$ and $\mathcal{I}(x) := (-\infty, x]$ if $x < 0$.

Given an $\mathbb{R}^d$ -valued Lévy process X and a nonempty set of indices $I \subset \{1, \dots, d\}$, the I margin of X is the Lévy process of lower dimension that contains only those components of X whose indices are in I : $X^I := (X^i)_{i \in I}$. The I -marginal tail integral U^I of X is then simply the tail integral of the process X^I .

Lévy Copulas: The General Case

Central to the theory of Lévy copulas are the notions of a d -increasing function and the margins of a d -increasing function. Intuitively speaking, a function F is d -increasing if dF is a positive measure on $\mathbb{R}^d$ in the sense of Lebesgue–Stieltjes integration. Similarly, the margin F^I is defined so that the measure $d(F^I)$ induced by F^I coincides with the I margin of the measure dF . Let us now turn to precise definitions.

We set $\overline{\mathbb{R}} := (-\infty, \infty]$ and for $a, b \in \overline{\mathbb{R}}^d$, we write $a \leq b$ if $a_k \leq b_k$, $k = 1, \dots, d$. In this case, $(a, b]$ denotes the interval

$$(a, b] := (a_1, b_1] \times \dots \times (a_d, b_d] \quad (3)$$

For a function $F : \overline{\mathbb{R}}^d \rightarrow \overline{\mathbb{R}}$, the F -volume of $(a, b]$ is defined by

$$V_F((a, b]) := \sum_{u \in \{a_1, b_1\} \times \dots \times \{a_d, b_d\}} (-1)^{N(u)} F(u) \quad (4)$$

where $N(u) := \#\{k : u_k = a_k\}$. In particular, $V_F((a, b]) = F(b) - F(a)$ for $d = 1$ and $V_F((a, b]) = F(b_1, b_2) + F(a_1, a_2) - F(a_1, b_2) - F(b_1, a_2)$ for

$d = 2$. If $F(u) = \prod_{i=1}^d u_i$, the F volume of any interval is equal to its Lebesgue measure.

A function $F : \overline{\mathbb{R}}^d \rightarrow \overline{\mathbb{R}}$ is called d increasing if $V_F((a, b]) \geq 0$ for all $a \leq b$. The distribution function of a random vector is one example of a d -increasing function. The tail integral U was defined in such way that $(-1)^d U$ is d increasing in every orthant (but not on the entire space).

Let $F : \overline{\mathbb{R}}^d \rightarrow \overline{\mathbb{R}}$ be a d -increasing function such that $F(u_1, \dots, u_d) = 0$ if $u_i = 0$ for at least one i . For an index set I , the I margin of F is the function $F^I : \overline{\mathbb{R}}^{|I|} \rightarrow \overline{\mathbb{R}}$, defined by

$$F^I((u_i)_{i \in I}) := \lim_{a \rightarrow \infty} \sum_{(u_i)_{i \in I^c} \in \{-a, \infty\}^{|I^c|}} \times F(u_1, \dots, u_d) \prod_{i \in I^c} \text{sgn } u_i \quad (5)$$

where $I^c := \{1, \dots, d\} \setminus I$. In particular, we have $F^{(1)}(u) = F(u, \infty) - \lim_{a \rightarrow -\infty} F(u, a)$ for $d = 2$. To understand the reasoning leading to the above definition of margins, note that any positive measure μ on $\overline{\mathbb{R}}^d$ naturally induces an increasing function F via

$$F(u_1, \dots, u_d) := \mu\left((u_1 \wedge 0, u_1 \vee 0] \times \dots \times (u_d \wedge 0, u_d \vee 0]\right) \prod_{i=1}^d \text{sgn } u_i \quad (6)$$

for $u_1, \dots, u_d \in \overline{\mathbb{R}}$. The margins of μ are usually defined by

$$\mu^I(A) = \mu\left(\{u \in \overline{\mathbb{R}}^d : (u_i)_{i \in I} \in A\}\right), \quad A \subset \overline{\mathbb{R}}^{|I|} \quad (7)$$

It is now easy to see that the margins of F are induced by the margins of μ in the sense of equation (6).

A function $F : \overline{\mathbb{R}}^d \rightarrow \overline{\mathbb{R}}$ is called *Lévy copula* if it satisfies the following four conditions (the first one is just a nontriviality requirement):

1. $F(u_1, \dots, u_d) \neq \infty$ for $(u_1, \dots, u_d) \neq (\infty, \dots, \infty)$;
2. $F(u_1, \dots, u_d) = 0$ if $u_i = 0$ for at least one $i \in \{1, \dots, d\}$;
3. F is d -increasing; and
4. $F^{(i)}(u) = u$ for any $i \in \{1, \dots, d\}$, $u \in \mathbb{R}$.

Lévy Copulas: The Spectrally One-sided Case

If X has only positive jumps in each component, or if we are only interested in the positive jumps of X , only the values $F(u_1, \dots, u_d)$ for $u_1, \dots, u_d \geq 0$ are relevant. We can then set $F(u_1, \dots, u_d) = 0$ if $u_i < 0$ for at least one i , which greatly simplifies the definition of the margins:

$$F^I((u_i)_{i \in I}) = F(u_1, \dots, u_d)|_{u_j = +\infty, j \notin I} \quad (8)$$

Taking the margins now amounts to replacing the variable that is being integrated out with infinity—exactly the same procedure as for probability distribution functions. Restricting a Lévy copula to $[0, \infty]^d$ in such way, we obtain a Lévy copula for spectrally positive Lévy processes, or, for short, a *positive Lévy copula*.

Sklar's Theorem for Lévy Processes

The following theorem [4, 7] characterizes the dependence structure of Lévy processes in terms of Lévy copulas:

Theorem 1

1. Let $X = (X^1, \dots, X^d)$ be a $\mathbb{R}^d$ -valued Lévy process. Then there exists a Lévy copula F such that the tail integrals of X satisfy

$$U^I((x_i)_{i \in I}) = F^I((U_i(x_i))_{i \in I}) \quad (9)$$

for any nonempty index set $I \subset \{1, \dots, d\}$ and any $(x_i)_{i \in I} \in (\mathbb{R} \setminus \{0\})^{|I|}$. The Lévy copula F is unique on $\prod_{i=1}^d \overline{\text{Ran } U_i}$.

2. Let F be a d -dimensional Lévy copula and $U_i, i = 1, \dots, d$, tail integrals of real-valued Lévy processes. Then there exists a $\mathbb{R}^d$ -valued Lévy process X whose components have tail integrals $U_1, \dots, U_d$ and whose marginal tail integrals satisfy equation (9) for any nonempty $I \subset \{1, \dots, d\}$ and any $(x_i)_{i \in I} \in (\mathbb{R} \setminus \{0\})^{|I|}$. The Lévy measure ν of X is uniquely determined by F and $U_i, i = 1, \dots, d$.

In particular, applying the above theorem with $I = \{1, \dots, d\}$, we obtain the usual formula

$$U(x_1, \dots, x_d) = F(U_1(x_1), \dots, U_d(x_d)) \quad (10)$$

If the one-dimensional marginal Lévy measures are infinite and have no atoms, $\text{Ran } U_i = (-\infty, 0) \cup (0, \infty)$ for any i and one can compute F directly via

$$F(u_1, \dots, u_d) = U(U_1^{-1}(u_1), \dots, U_d^{-1}(u_d)) \quad (11)$$

Examples and Parametric Families

The components of a pure-jump Lévy process are independent if and only if they never jump together, that is, if the Lévy measure is supported by the coordinate axes. This leads to a characterization of Lévy processes with independent components in terms of their Lévy copulas: the components $X^1, \dots, X^d$ of a $\mathbb{R}^d$ -valued Lévy process X are independent if and only if their Brownian motion parts are independent and if X has a Lévy copula of the form

$$F_{\perp}(x_1, \dots, x_d) := \sum_{i=1}^d x_i \prod_{j \neq i} 1_{\{\infty\}}(x_j) \quad (12)$$

The Lévy copula of independence is thus different from the copula of independent random variables $C_{\perp}(u_1, \dots, u_d) = u_1 \dots u_d$, which emphasizes the fact that the two notions are far from being the same and the “copula” intuition cannot always be applied to Lévy copulas.

The complete dependence copula, on the other hand, turns out to have a similar form to the classical case. Recall that a subset S of $\mathbb{R}^d$ is called *ordered* if, for any two vectors $u, v \in S$, either $u_k \leq v_k$, $k = 1, \dots, d$ or $u_k \geq v_k$, $k = 1, \dots, d$. Similarly, S is called *strictly ordered* if, for any two different vectors $u, v \in S$, either $u_k < v_k$, $k = 1, \dots, d$ or $u_k > v_k$, $k = 1, \dots, d$. Furthermore, set

$$K := \{x \in \mathbb{R}^d : \text{sgn } x_1 = \dots = \text{sgn } x_d\} \quad (13)$$

The jumps of an $\mathbb{R}^d$ -valued Lévy process X are said to be *completely dependent* or *comonotonic* if there exists a strictly ordered subset $S \subset K$ such that $\Delta X_t := X_t - X_{t-} \in S$, $t \in \mathbb{R}_+$ (except for some null set of paths). The condition $\Delta X_t \in K$ means that if the components of a Lévy process are comonotonic, they always jump in the same direction. A $\mathbb{R}^d$ -valued Lévy process whose Lévy measure is supported by an ordered set $S \subset K$ is described by the *complete*

dependence Lévy copula given by

$$F_{\parallel}(x) := \min(|x_1|, \dots, |x_d|) 1_K(x) \prod_{i=1}^d \text{sgn } x_i \quad (14)$$

Conversely, if $F_{\parallel}$ is a Lévy copula of X , then the Lévy measure of X is supported by an ordered subset of K . If, in addition, the tail integrals U_i of X^i are continuous and satisfy $\lim_{x \rightarrow 0} U_i(x) = \infty$, $i = 1, \dots, d$, then $F_{\parallel}$ is the unique Lévy copula of X and the jumps of X are completely dependent. For positive Lévy copulas, expression (14) simplifies to

$$F_{\parallel}(x_1, \dots, x_d) := \min(x_1, \dots, x_d) \quad (15)$$

that is, we recover the expression of the complete dependence copula of random variables (but the two functions are defined on different domains!).

One simple and convenient parametric family of positive Lévy copulas is similar to the Clayton family of copulas; it is therefore called the *Clayton–Lévy copula*:

$$F(u_1, \dots, u_d) = \left(\sum_{i=1}^d u_i^{-\theta} \right)^{-1/\theta}, \quad u_1, \dots, u_d \geq 0 \quad (16)$$

The reader can easily check that this copula converges to the complete dependence copula $F_{\parallel}$ as $\theta \rightarrow \infty$ and to the independence copula $F_{\perp}$ as $\theta \rightarrow 0$. This construction can be generalized to a Lévy copula on $\mathbb{R}^d$:

$$F(u_1, \dots, u_d) = 2^{2-d} \left(\sum_{i=1}^d |u_i|^{-\theta} \right)^{-1/\theta} \times (\eta 1_{\{u_1 \dots u_d \geq 0\}} - (1 - \eta) 1_{\{u_1 \dots u_d < 0\}}) \quad (17)$$

defines a two-parameter family of Lévy copulas. The role of the parameters is easiest to analyze in the case $d = 2$, when equation (17) becomes

$$F(u, v) = (|u|^{-\theta} + |v|^{-\theta})^{-1/\theta} \times (\eta 1_{\{uv \geq 0\}} - (1 - \eta) 1_{\{uv < 0\}}) \quad (18)$$

From this equation, it is readily seen that the parameter η determines the dependence of the *sign* of jumps: when $\eta = 1$, the two components always jump in the

same direction, and when $\eta = 0$, positive jumps in one component are accompanied by negative jumps in the other and *vice versa*. The parameter θ is responsible for the dependence of absolute values of jumps in different components.

Figure 1 shows the scatter plots of weekly returns in an exponential Lévy model with variance gamma (see **Variance-gamma Model**) margins and the dependence pattern given by the Lévy copula (18) with two different sets of dependence parameters,

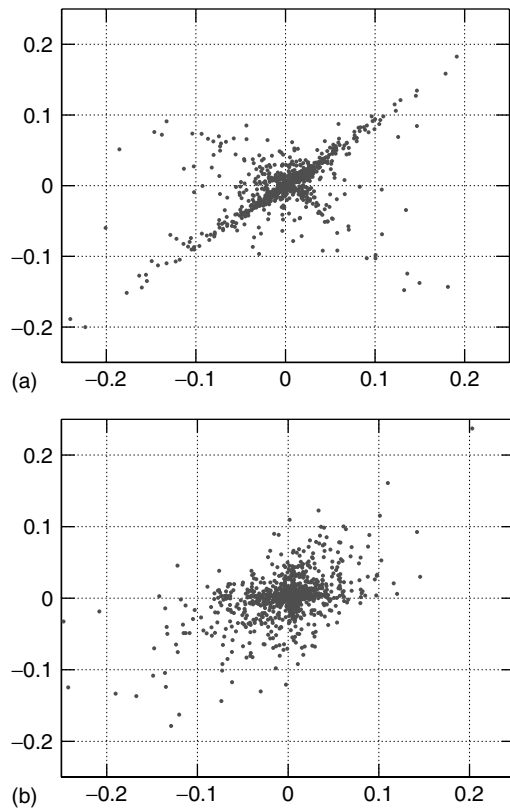

Figure 1 Scatter plots of returns in a two-dimensional variance gamma model with correlation $\rho = 50\%$ and different tail dependence. (a) Strong tail dependence ($\eta = 0.75$ and $\theta = 10$) and (b) weak tail dependence ($\eta = 0.99$ and $\theta = 0.61$)

both of which lead to a correlation of 50% but have different tail dependence patterns. It is clear that when a precise description of tail events such as simultaneous large jumps is necessary, Lévy copulas offer more freedom in modeling dependence than traditional correlation-based approaches. A natural application of Lévy copulas arises in the context of multidimensional gap options [8] that are exotic products whose payoff depends on the total number of sharp downside moves in a basket of assets.

Convex Duality

Convex duality refers to a general principle that allows us to associate with an original minimization program (the *primal problem*) a class of concave maximization concave programs (the *dual problem*), which, under some conditions, are equivalent to the primal. The unifying principles underlying these methods can be traced back to the basic duality that exists between a convex set of points in the plane and the set of supporting lines (hyperplanes). Duality tools can be applied to nonconvex programs too, but are most effective for convex problems.

Convex optimization problems naturally arise in many areas of finance; we mention just few of them (see the list of the related entries at the end of this article): maximization of expected utility in complete or incomplete markets, mean–variance portfolio selection and CAPM, utility indifference pricing, selection of the minimal entropy martingale measure, and model calibration. This short and nonexhaustive list should give a hint of the scope of convex duality methods in financial applications.

Consider the following *primal* minimization (convex) problem:

$$\begin{aligned} \text{(P)} : \quad & \min f(v) \\ \text{subject to} \quad & v \in A \end{aligned} \quad (1)$$

where A is a convex subset of some vector space V and $f : A \rightarrow \mathbb{R}$ is a convex function. Convex duality principles consist in pairing this problem with a *dual* maximization (concave) problem:

$$\text{(D)} : \quad \max g(w) \quad \text{sub } w \in B \quad (2)$$

where B is a convex subset of some other vector space W (possibly $W = V$) and $g : B \rightarrow \mathbb{R}$ is a concave function.

In general, by applying a duality principle, we usually try to

1. find a lower bound for the value of the primal problem, or, better
2. find the value of the primal problem, or, even better
3. find the solutions, if any, of the primal problem.

Different duality principles differ in the way the dual problem is built. Two main principles are Lagrange duality and Fenchel duality. Even though they are formally equivalent, at least in the finite-dimensional case, they provide different insights into the problem. We will see below how the Lagrange and Fenchel duality principles practically accomplish the tasks 1 to 3 above.

For the topics to be presented below, comprehensive references are [4] and [1] for the finite-dimensional case ([1] also provides an extensive account of numerical methods) and [2] for the infinite-dimensional case.

Lagrange Duality in Finite-dimensional Problems

We consider finite-dimensional problems, that is, $V = \mathbb{R}^N$ for some $N \geq 1$. We denote $v \cdot w$ the inner product between two vectors $v, w \in \mathbb{R}^N$ and use $v \geq 0$ as a shorthand for $v_n \geq 0 \quad \forall n$. Let $f, h_1, \dots, h_M : C \rightarrow \mathbb{R}$ be $M + 1$ convex functions, where $C \subseteq \mathbb{R}^N$ is a convex set. Setting $h = (h_1, \dots, h_M)$, so that h is a convex function from C to $\mathbb{R}^M$, we consider, as the primal problem, the minimization of f under M inequality constraints:

$$\begin{aligned} \text{(P)} : \quad & \min f(v) \quad \text{sub } v \in A \\ & = \{v \in C : h(v) \leq 0\} \subset \mathbb{R}^N \end{aligned} \quad (3)$$

To build a dual problem, we define the so-called Lagrangian function

$$\begin{aligned} \mathcal{L}(v, w) &:= f(v) + w \cdot h(v) \\ v &\in C, \quad w \in \mathbb{R}^M \end{aligned} \quad (4)$$

and note that $f(v) = \sup_{w \geq 0} \mathcal{L}(v, w)$ for any $v \in A$. As a consequence, we can write the primal problem in terms of $\mathcal{L}$:

$$\text{(P)} : \quad \inf_{v \in C} \sup_{w \geq 0} \mathcal{L}(v, w) \quad (5)$$

The dual problem is then defined by switching the supremum with the infimum

$$\text{(D)} : \quad \sup_{w \geq 0} \inf_{v \in C} \mathcal{L}(v, w) \quad (6)$$

In the terminology of the introductory section, the dual problem is then

$$(D) : \quad \max g(w) \quad \text{sub } w \in B \\ = \{w \in D : w \geq 0\} \subset \mathbb{R}^M \quad (7)$$

where

$$g(w) = \inf_{v \in C} \mathcal{L}(v, w) \quad (8)$$

and $D = \{w \in \mathbb{R}^M : g(w) > -\infty\}$ is the domain of g . It can be proved that D is a convex set and g is a concave function on D even if f is not convex: therefore *the dual problem is always concave*, even when the primal problem is not convex.

We assume throughout *primal and dual feasibility*, that is, A and B are assumed to be nonempty. Dual feasibility would however be ensured under Slater conditions for A (see below). Let $p = \inf_A f$ and $d = \sup_B g$ be the (possibly infinite) values of the primal and the dual. A *primal (dual) solution* is $\hat{v} \in A$ ($\hat{w} \in B$), if any, such that $f(\hat{v}) = p$ ($g(\hat{w}) = d$); a *solution pair* is a feasible pair $(\hat{v}, \hat{w}) \in A \times B$ made by a primal and a dual solution.

Lagrange Duality Theorem

1. Weak duality

Primal boundedness ($p > -\infty$) implies dual boundedness ($d < +\infty$) and

$$p \geq d \quad (p - d \geq 0 \text{ is called the duality gap}) \quad (9)$$

Moreover, if there is no duality gap ($p = d$), then $(\hat{v}, \hat{w}) \in A \times B$ is a solution pair if and only if

$$\hat{w} \cdot h(\hat{v}) = 0 \quad \text{and} \quad \mathcal{L}(\hat{v}, \hat{w}) = g(\hat{w}) \quad (10)$$

In this case, $\hat{w}$ is usually called a Lagrange multipliers vector.

2. Strong duality

If, in addition, there exists $v \in C$ such that $h_m(v) < 0$ for all m (Slater condition), then there is no duality gap and there exists a dual solution.

See [4] or [1] for a proof.

Weak duality, whose proof is trivial, holds under very general conditions: in particular, the primal problem need not be convex. It gives a lower bound for the value of the primal problem, which is useful in many

practical situations, “branch and bound” algorithms in integer programming being a prominent example. It also provides a workable condition that characterizes a solution pair, at least when there is no duality gap.

Strong duality, on the contrary, requires a precise topological assumption: the interior of the constraint set has to be nonempty (Slater condition). We note, however, that this condition is satisfied in most cases, at least in the present finite-dimensional setting. The proof is then based on a separating hyperplane theorem, that in turn requires convexity assumptions about f and h . When strong duality holds, and provided we are able to actually solve the dual problem, we obtain the exact value of the primal (no duality gap).

We can add a finite number (say L) of linear equality constraints to (P), obtaining

$$(P) : \quad \min f(v) \quad \text{sub } v \in A \\ = \{v \in C : h(v) \leq 0, Qv = r\} \subset \mathbb{R}^N \quad (11)$$

where Q is an $L \times N$ matrix and $r \in \mathbb{R}^L$. The Lagrangian is defined as

$$\mathcal{L}(v, w) = f(v) + w^{\text{in}} \cdot h(v) + w^{\text{eq}} \cdot (Qv - r) \\ v \in C, w = (w^{\text{in}}, w^{\text{eq}}) \in \mathbb{R}^{M \times L} \quad (12)$$

in such a way that

$$\inf_{v \in A} f(v) = \inf_{v \in C} \sup_{w^{\text{in}} \geq 0, w^{\text{eq}} \in \mathbb{R}^L} \mathcal{L}(v, w) \quad (13)$$

The dual problem is then

$$(D) : \quad \max g(w) \quad \text{sub } w \in B \\ = \{w \in D : w^{\text{in}} \geq 0\} \subset \mathbb{R}^{M \times L} \quad (14)$$

where, as before, $g(w) = \inf_{v \in C} \mathcal{L}(v, w)$, and D is the domain of g . It is worth noting that if the primal problem has equality constraints only, then the only constraint of the dual problem is $w \in D$.

A Lagrange duality theorem can then be stated and also proved in this case, reaching similar conclusions. We have just to replace $\hat{w}$ with $\hat{w}^{\text{in}}$ in the first condition in (10), and modify the Slater condition as follows:

- *There exists $v \in \text{ri}(C)$ such that $h_m(v) < 0$ for all m and $Qv = r$* (15)

The relative interior $\text{ri}(C)$ is the interior of the convex set C relative to the affine hull of C . For instance, if $C = [0, 1] \times \{0\} \subset \mathbb{R}^2$, then $\text{ri}(C) = (0, 1) \times \{0\}$ (because the affine hull of C is $\mathbb{R} \times \{0\}$), while the interior of C is clearly empty (see [4] for more on relative interiors and related topics about convex sets).

In many concrete problems, C is a polyhedron, that is, it is the (convex and closed) set defined by a certain finite set of linear inequalities, and all the functions h_m are affine. If we assume, in addition, that f may be extended to a finite convex function over *all* $\mathbb{R}^N$, Farkas Lemma allows us to prove strong duality without requiring any Slater condition. Remarkably, if f is linear too, then the existence of a primal solution is ensured.

The Lagrange duality theorem provides us a simple criterion for the existence of a dual solution and a set of conditions characterizing a possible primal solution. It is, however, not directly concerned with the *existence* of a primal solution. To ensure this, one has to assume stronger conditions such as compactness of C or coercivity of f . A third condition (f linear) has been described above.

We have seen that the dual problem usually looks much better than the primal: it is always concave and its solvability is guaranteed under mild assumptions about the primal. This fact is particularly useful in designing numerical procedures. Moreover, even when the primal is solvable, the dual often proves easier to handle. We provide a simple example that should clarify the point.

A standard linear programming (LP) problem comes, by definition, in the form

$$(P) : \quad \min c \cdot v \quad \text{sub } Qv = r, \quad v \geq 0, \quad v \in \mathbb{R}^N \quad (16)$$

where $c \in \mathbb{R}^N$, Q is a $L \times N$ matrix and $r \in \mathbb{R}^L$. An easy computation shows that the dual problem is (T denotes transposition)

$$(D) : \quad \max r \cdot w \quad \text{sub } Q^T w \leq c, \quad w \in \mathbb{R}^L \quad (17)$$

We know that strong duality holds in this case, and that the existence of a solution pair is guaranteed. In particular, $(Q^T \hat{w} - c) \cdot \hat{v} = 0$ is a necessary condition for a pair $(\hat{v}, \hat{w})$ to be a solution. The dual problem, however, has L variables and N constraints and thus can often be more tractable than the primal

if N is much larger than L . This is the basis for great enhancements in existing numerical methods.

A last remark concerns the word “duality”: any dual problem can be turned into an equivalent minimization primal problem. It turns out that the bidual, that is, the dual of this new primal problem, seldom coincides with the original primal problem. LP problems are an important exception: the bidual of an LP problem is the problem itself.

Fenchel Duality in Finite-dimensional Problems

Fenchel duality, that we will derive from Lagrange duality, may be applied to primal problems in the form

$$(P) : \quad \min \{f_1(v) - f_2(v)\} \\ \text{sub } v \in A = C_1 \cap C_2 \subset \mathbb{R}^N \quad (18)$$

where $C_1, C_2 \subseteq \mathbb{R}^N$ are convex, $f_1 : C_1 \rightarrow \mathbb{R}$ is convex, and $f_2 : C_2 \rightarrow \mathbb{R}$ is concave.

Consider the function $f(x, y) = f_1(x) - f_2(y)$ defined on $\mathbb{R}^{2N}$ and clearly convex. We can restate the primal as

$$(P) : \quad \min f(x, y) \quad \text{sub } (x, y) \in A' \\ = \{(x, y) \in C_1 \times C_2 : x = y\} \subset \mathbb{R}^{2N} \quad (19)$$

where the N fictitious linear constraints $(x_n = y_n \forall n)$ allow us to apply the Lagrange duality machinery. The Lagrangian function is $\mathcal{L}(x, y, w) = f_1(x) - f_2(y) + w \cdot (x - y)$ and, using some simple algebra, we compute

$$g(w) = \inf_{x \in C_1, y \in C_2} \mathcal{L}(x, y, w) = f_2^*(w) - f_1^*(w) \quad (20)$$

where

$$f_1^*(w) = \sup_{x \in C_1} \{w \cdot x - f_1(x)\} \quad (21)$$

is, by definition, the convex conjugate (indeed, f_1^* is convex) of the convex function f_1 , and

$$f_2^*(w) = \inf_{y \in C_2} \{w \cdot y - f_2(y)\} \quad (22)$$

is the concave conjugate (indeed, f_2^* is concave) of the concave function f_2 . As a consequence, the dual problem is

$$(D) : \max \{f_2^*(w) - f_1^*(w)\} \\ \text{sub } w \in B = C_1^* \cap C_2^* \subset \mathbb{R}^N \quad (23)$$

where C_1^* and C_2^* are the domains of f_1^* and f_2^* , respectively. Assuming primal feasibility and boundedness, the Lagrange duality theorem yields the Fenchel duality theorem.

Fenchel Duality Theorem

1. Weak duality

If there is no duality gap, $(\hat{v}, \hat{w})$ is a solution pair if and only if

$$\hat{v} \cdot \hat{w} = f_1(\hat{v}) + f_1^*(\hat{w}) = f_2(\hat{v}) + f_2^*(\hat{w}) \quad (24)$$

2. Strong duality

There is no duality gap between the primal and the dual, and there is a dual solution, provided one of the following conditions is satisfied:

- (a) $\text{ri}(C_1) \cap \text{ri}(C_2)$ is nonempty
- (b) C_1 and C_2 are polyhedra and f_1 (resp. f_2) may be extended to a finite convex (concave) function over all $\mathbb{R}^N$

See [4] or [1] for a proof.

We say that a convex function f is closed if, for any $a \in \mathbb{R}$, the set $\Gamma_a = \{v : f(v) \leq a\}$ is closed; a similar definition applies to concave functions, where the inequality inside Γ_a is reversed. A sufficient, though not necessary condition for f to be closed is continuity on all C . A celebrated result (the Fenchel–Moreau theorem) states that $(f^*)^* \equiv f$, provided f is a closed (convex or concave) function. Therefore, if in the primal problem f_1 and f_2 are closed, then the dual problem of the dual coincides with the primal, and the duality is therefore *complete*. Thanks to this fact, an application of the Fenchel duality theorem to the dual problem allows us to state that the primal has a solution provided one of the following conditions is satisfied:

1. $\text{ri}(C_1^*) \cap \text{ri}(C_2^*)$ is nonempty.
2. C_1^* and C_2^* are polyhedra, and f_1^* (resp. f_2^*) may be extended to a finite convex (concave) function over all $\mathbb{R}^N$.

Fenchel duality can sometimes be effectively used for general problems in the form

$$(P) : \min f(v) \quad \text{sub } v \in C \subset \mathbb{R}^N \quad (25)$$

where f and C are convex. Indeed, such a problem can be cast in the form (18) provided we set $f_1 = f$, $f_2 = 0$ (concave), $C_1 = \mathbb{R}^N$, and $C_2 = C$. The dual problem is given by equation (23), where

$$f_1^*(w) = \sup_{v \in \mathbb{R}^N} \{w \cdot v - f(v)\} \quad (26)$$

is an unconstrained problem and

$$f_2^*(w) = \inf_{v \in C} w \cdot v \quad (27)$$

has a simple goal function.

We have derived Fenchel duality as a by product of Lagrange duality. However, it is possible to go in the opposite direction, by first proving Fenchel duality (unsurprisingly, using hyperplane separation arguments, see [2]) and then writing a Lagrange problem in the Fenchel form, so that Lagrange duality can be derived (see [3]). Therefore, at least in the finite-dimensional setting, Lagrange and Fenchel duality are formally equivalent.

Duality in Infinite-dimensional Problems

For infinite-dimensional problems, Lagrange or Fenchel duality exhibit a large formal similarity with the finite-dimensional counterparts we have described so far. Nevertheless, the technical topological assumptions, which are needed to ensure duality, become much less trivial when the space $V = \mathbb{R}^N$ is replaced by an infinite-dimensional Banach space. We give a brief account of these differences.

Let V be a Banach space and consider the primal problem

$$(P) : \min f(v) \quad \text{sub } v \in A \\ = \{v \in C : h(v) \leq 0\} \subset V \quad (28)$$

where $C \subseteq V$ is a convex set, and $f : C \rightarrow \mathbb{R}$ and $h : C \rightarrow \mathbb{R}^M$ are convex functions. Then, by mimicking the finite-dimensional case, the dual problem is

$$(D) : \max g(w) \quad \text{sub } w \in B \\ = \{w \in D : w \geq 0\} \subset \mathbb{R}^M \quad (29)$$

where $g(w) = \inf_{v \in C} \{f(v) + w \cdot h(v)\}$, and D is the domain of g . We can note that the dual is finite-dimensional, but the definition of g involves an infinite-dimensional problem. A perfect analog of the finite-dimensional Lagrange duality theorem may be derived in this more general case too (see [2]) with essentially the same Slater condition (existence of some $v \in C$ such that $h_m(v) < 0$ for any m). We can also introduce a finite set of linear inequalities: this case can be handled in exactly the same way as in the finite-dimensional case. However, the hypothesis $\text{ri}(C) \neq \emptyset$ is not completely trivial here.

Fenchel duality too can be much generalized. Indeed, let V be a Banach space, $W = V^*$ its dual space (the Banach space of continuous linear forms on V), and denote by $\langle v, v^* \rangle$ the action of $v^* \in V^*$ on $v \in V$. Consider the primal problem

$$\begin{aligned} (\text{P}) : \quad & \min \{f_1(v) - f_2(v)\} \quad \text{sub } v \in A \\ & = C_1 \cap C_2 \subset V \end{aligned} \quad (30)$$

where $C_1, C_2 \subseteq V$ are convex sets, f_1 is convex on C_1 , and f_2 is concave on C_2 . Then, again by mimicking the finite-dimensional case, we associate the primal with the dual

$$\begin{aligned} (\text{D}) : \quad & \max \{f_2^*(v^*) - f_1^*(v^*)\} \quad \text{sub } v^* \in B \\ & = C_1^* \cap C_2^* \subset V^* \end{aligned} \quad (31)$$

where

$$\begin{aligned} f_1^*(v^*) &= \sup_{v \in C_1} \{\langle v, v^* \rangle - f_1(v)\} \quad \text{and} \quad f_2^*(v^*) \\ &= \inf_{v \in C_2} \{\langle v, v^* \rangle - f_2(v)\} \end{aligned} \quad (32)$$

are the convex and concave conjugates of f_1 and f_2 , respectively, and C_1^* and C_2^* are their domains. Then, with obvious formal modifications, Fenchel duality theorem holds in this case, too (see again [2]). However, to obtain strong duality, we must supplement conditions (a) or (b) with the following

- Either $\{(v, a) \in V \times \mathbb{R} : f_1(v) \leq a\}$
or $\{(v, a) \in V \times \mathbb{R} : f_2(v) \geq a\}$
has a nonempty interior.

This latter condition, which, in the finite-dimensional setting, follows from (a) or (b), must be checked separately in the present case.

Squared Bessel Processes

Squares of Bessel processes enjoy both an additivity property and a scaling property, which are, arguably, the main reasons why these processes occur naturally in a number of Brownian, or linear diffusion, studies. This survey is written in a minimalist manner; the aim is to refer the reader to a few references where many facts and formulae are discussed in detail.

Squared Bessel (BESQ) Processes

A squared Bessel (BESQ) process $(X_t^{(x,\delta)}, t \geq 0)$ may be defined (in law) as the solution of the stochastic differential equation:

$$X_t = x + 2 \int_0^t \sqrt{X_s} d\beta_s + \delta t, \quad X_t \geq 0 \quad (1)$$

where x is the starting value: $X_0 = x$, δ is the so-called dimension of X , and $(\beta_s)_{s \geq 0}$ is standard Brownian motion. For any integer dimension δ , $(X_t, t \geq 0)$ may be obtained as the square of the Euclidean norm of δ -dimensional Brownian motion.

The general theory of stochastic differential equations (SDEs) ensures that equation (1) enjoys pathwise uniqueness, hence uniqueness in law, and consequently the strong Markov property. Denoting by Q_x^δ the law of $(X_t)_{t \geq 0}$, solution of equation (1), on the canonical space $C_+ \equiv C(\mathbb{R}_+, \mathbb{R}_+)$, where $(Z_u, u \geq 0)$ is taken as the coordinate process, there is the convolution property:

$$Q_x^\delta * Q_{x'}^{\delta'} = Q_{x+x'}^{\delta+\delta'} \quad (2)$$

which holds for all $x, \delta \geq 0$ ([7]); in other terms, adding two independent BESQ processes yields another BESQ process, whose starting point, respectively dimension, is the sum of the starting points, respectively dimensions.

It follows from equation (2) that for any positive measure $\mu(du)$ on $\mathbb{R}_+$ such that $\int \mu(du)(1+u) < \infty$, then, if $I_\mu = \int \mu(du)Z_u$,

$$Q_x^\delta \left(\exp - \frac{1}{2} I_\mu \right) = (A_\mu)^\delta (B_\mu)^x \quad (3)$$

with $A_\mu = (\phi_\mu(\infty))^{1/2}$; $B_\mu = \exp(\phi'_\mu(0+))$ for ϕ_μ , the unique decreasing solution of the Sturm–Liouville equation: $\phi'' = \phi\mu$; $\phi(0) = 1$.

Equation (3) may be considered as the (generalized) Laplace transform (with argument μ) of the probability Q_x^δ , while as Q_x^δ , for any fixed δ and x , is infinitely divisible, the next formula is the Lévy Khintchine representation of Q_x^δ :

$$Q_x^\delta \left(\exp - \frac{1}{2} I_\mu \right) = \exp \left(- \int_{C_+} M_{x,\delta}(dz) \left(1 - e^{-\frac{1}{2} I_\mu(z)} \right) \right) \quad (4)$$

where $M_{x,\delta} = xM + \delta N$, for M and N two σ -finite measures on C_+ , which are described in detail in, for example, [5] and [6].

Brownian Local Times and BESQ Processes

The Ray–Knight theorems for Brownian local times $(L_t^y; y \in \mathbb{R}, t \geq 0)$ express the laws of $(L_T^y; y \in \mathbb{R})$ for some very particular stopping times in terms of certain Q_x^δ 's, namely,

1. if $T = T_a$ is the first hitting time of a by Brownian motion then $\tilde{Z}_y^{(a)} \equiv L_{T_a}^{a-y}$, $y \geq 0$, satisfies the following:

$$\tilde{Z}_y = 2 \int_0^y \sqrt{\tilde{Z}_z} d\beta_z + 2(y \wedge a) \quad (5)$$

2. if $T = \tau_\ell$ is the first time $(L_t^0, t \geq 0)$ the Brownian local time at level 0 reaches ℓ , then $(L_{\tau_\ell}^y, y \geq 0)$ and $(L_{\tau_\ell}^{-y}, y \geq 0)$ are two independent BESQ processes, distributed as Q_ℓ^0 .

An Implicit Representation in Terms of Geometric Brownian Motions

Lamperti [3] showed a one-to-one correspondence between Lévy processes $(\xi_t, t \geq 0)$ and semistable Markov processes $(\Sigma_u, u \geq 0)$ via the (implicit) formula:

$$\exp(\xi_t) = \Sigma \int_0^t ds \exp(\xi_s), \quad t \geq 0 \quad (6)$$

In the particular case where $\xi_t = 2(B_t + \nu t)$, $t \geq 0$, formula (6) becomes

$$\exp(2(B_t + \nu t)) = X^{(1,\delta)} \int_0^t ds \exp(2(B_s + \nu s)) \quad (7)$$

where, in agreement with our notation, $(X_u^{(1,\delta)}, u \geq 0)$ denotes a BESQ process starting from 1 with dimension $\delta = 2(1 + \nu)$. We note that in equation (7), δ may be negative, that is, $\nu < -1$; however, formula (7) reveals $(X_u^{(1,\delta)})$ for $u \leq T_0(X^{(1,\delta)})$ the first hitting time of 0 by $(X^{(1,\delta)})$. Nonetheless, the study of BESQ^δ , for any $\delta \in \mathbb{R}$, has been developed in [1].

Absolute continuity relationships between the laws of different BESQ processes may be derived from equation (7), combined with the Cameron–Martin relationship between the laws of $(B_t + \nu t, t \geq 0)$ and $(B_t, t \geq 0)$.

Precisely, one obtains thus, for $\delta \geq 2$:

$$\mathcal{Q}_{x|Z_u}^\delta = \left(\frac{Z_u}{x}\right)^{\frac{\nu}{2}} \exp\left(-\frac{\nu^2}{2} \int_0^u \frac{ds}{Z_s}\right) \cdot \mathcal{Q}_{x|Z_u}^2 \quad (8)$$

where $Z_u \equiv \sigma\{Z_s, s \leq u\}$, and $\nu = \frac{\delta}{2} - 1$. The combination of equations (7) and (8) may be used to derive results about $(B_t + \nu t, t \geq 0)$ from results about $X^{x,\delta}$ (and *vice versa*). In particular, the law of

$$A_{T_\lambda}^{(\nu)} := \int_0^{T_\lambda} ds \exp(2(B_s + \nu s)) \quad (9)$$

where T_λ denotes an independent exponential time, was derived in ([8], Paper #2) from this combination.

Some Explicit Formulae for BESQ Functionals

Formula (3), when μ is replaced by $\lambda\mu$, for any scalar $\lambda \geq 0$, yields the explicit Laplace transform

of I_μ , provided the function $\phi_{\lambda,\mu}$ is known explicitly, which is the case for $\mu(dt) = at^\alpha 1_{(t \leq A)} dt + b\varepsilon_A(dt)$ and many other examples.

Consequently, the semigroup of BESQ may be expressed explicitly in terms of Bessel functions, as well as the Laplace transforms of first hitting times (see, for example, [2]) and distributions of last passage times (see, for example, [4]). Chapter XI of [6] is entirely devoted to Bessel processes.

Semimartingale

Semimartingales form an important class of processes in probability theory, especially in the theory of **stochastic integration** and its applications. They serve as natural models for asset pricing, since under no-arbitrage assumptions a price process must be a semimartingale [1, 3].

Let $(\Omega, \mathcal{F}, \mathbb{F} = (\mathcal{F}_t)_{t \geq 0}, P)$ be a complete probability space that satisfies the *usual assumptions* (i.e., $\mathcal{F}_0$ contains all P -null sets of $\mathcal{F}$ and the filtration $\mathbb{F}$ is right continuous). A càglàd, adapted process X is called a *semimartingale* if it admits a decomposition

$$X_t = X_0 + A_t + M_t \quad (1)$$

where X_0 is $\mathcal{F}_0$ -measurable, A is a process with finite variation, M is a local martingale, and $A_0 = M_0 = 0$. If, moreover, A is predictable (i.e., measurable with respect to the σ -algebra generated by all left-continuous processes), X is called a *special semimartingale*. In this case, the decomposition (1) is unique and we call it the *canonical decomposition*. Clearly, the set of all semimartingales is a vector space.

For any $a > 0$, a semimartingale X can be further decomposed as

$$X_t = X_0 + A_t + D_t + N_t \quad (2)$$

where D and N are local martingales such that D is a process with finite variation and the jumps of N are bounded by $2a$ (see [6] p. 126).

Alternatively, semimartingales can be defined as a class of “good integrators”. Let S be a collection of all simple predictable processes equipped with the uniform convergence in (t, ω) . A process H is called *simple predictable* if it has the representation

$$H_t = H_0 1_{\{0\}}(t) + \sum_{i=1}^n H_i 1_{(T_i, T_{i+1}]}(t) \quad (3)$$

where $0 = T_1 \leq \dots \leq T_{n+1} < \infty$ are stopping times, H_i are $\mathcal{F}_{T_i}$ -measurable and $|H_i| < \infty$ almost surely. Let L^0 be the space of (finite-valued) random variables topologized by convergence in probability. For a given process X , we define a linear mapping (*stochastic integral*) $I_X : S \rightarrow L^0$ by

$$I_X(H) = H_0 X_0 + \sum_{i=1}^n H_i (X_{T_{i+1}} - X_{T_i}) \quad (4)$$

A process X is defined to be a semimartingale if it is càglàd, adapted, and the mapping $I_X : S \rightarrow L^0$ is continuous. Such processes are “good integrators”, because they satisfy the following bounded convergence theorem: the uniform convergence of H^n to H (in S) implies the convergence in probability of $I_X(H^n)$ to $I_X(H)$. As a consequence, when X is a semimartingale, the domain of the stochastic integral I_X can be extended to the space of all predictable processes H (*see Stochastic Integrals*).

Indeed, these two definitions are equivalent. This result is known as the *Bichteler–Dellacherie theorem* [2, 4].

Examples

- Càglàd adapted processes with finite variation are semimartingales.
- All càglàd, adapted martingales, submartingales, and supermartingales are semimartingales.
- Brownian motion is a continuous martingale. Hence, it is a semimartingale.
- **Lévy processes** are semimartingales.
- Itô diffusions of the form

$$X_t = X_0 + \int_0^t a_s ds + \int_0^t \sigma_s dW_s \quad (5)$$

where W is a Brownian motion, are (continuous) semimartingales. In particular, solutions of stochastic differential equations of the type $dX_t = a(t, X_t)dt + \sigma(t, X_t)dW_t$ are semimartingales.

Quadratic Variation of Semimartingales

Quadratic variation is an important characteristic of a semimartingale. It is also one of the crucial objects in financial econometrics as it serves as a measure of the variability of a price process.

Let X, Y be semimartingales. The quadratic variation process $[X, X] = ([X, X]_t)_{t \geq 0}$ is given as

$$[X, X]_t = X_t^2 - X_0^2 - 2 \int_0^t X_{s-} dX_s \quad (6)$$

where $X_{s-} = \lim_{u < s, u \rightarrow s} X_u$ ($X_{0-} = X_0$). The quadratic covariation of X and Y is defined by

$$[X, Y]_t = X_t Y_t - X_0 Y_0 - \int_0^t X_{s-} dY_s - \int_0^t Y_{s-} dX_s \quad (7)$$

which is also known as the *integration by parts* formula (see [5] p. 51). Obviously, the operator $(X, Y) \rightarrow [X, Y]$ is symmetric and bilinear. We therefore have the polarization identity

$$[X, Y] = \frac{1}{2}([X + Y, X + Y] - [X, X] - [Y, Y]) \quad (8)$$

The quadratic (co-)variation process has the following properties:

1. $\Delta[X, Y] = \Delta X \Delta Y$ with $\Delta Z_s = Z_s - Z_{s-}$ ($\Delta Z_0 = 0$) for any càglàd process Z .
2. $[X, Y]$ has finite variation and $[X, X]$ is an increasing process.
3. Let A, B be càglàd, adapted processes. Then it holds that

$$\left[\int_0^t A_s dX_s, \int_0^t B_s dY_s \right]_t = \int_0^t A_s B_s d[X, Y]_s \quad (9)$$

Furthermore, the quadratic variation process can be written as a sum of its continuous and discontinuous parts:

$$[X, X]_t = [X, X]_t^c + \sum_{0 \leq s \leq t} |\Delta X_s|^2 \quad (10)$$

where $[X, X]^c$ denotes the continuous part of $[X, X]$. A semimartingale X is called *quadratic pure jump* if $[X, X]^c = 0$.

For any subdivision $0 = t_0^n < \dots < t_{k_n}^n = t$ with $\max_i |t_i^n - t_{i-1}^n| \rightarrow 0$, it holds that

$$\sum_{i=1}^{k_n} (X_{t_i^n} - X_{t_{i-1}^n})(Y_{t_i^n} - Y_{t_{i-1}^n}) \xrightarrow{P} [X, Y]_t \quad (11)$$

The latter suggests the *realized variance* as a natural consistent estimator of the quadratic variation (see **Realized Volatility and Multipower Variation**).

Stability Properties of Semimartingales

Semimartingales turn out to be invariant under change of measure. Indeed, if Q is a probability measure that is absolutely continuous with respect to P , then every P -semimartingale is a Q -semimartingale. When X is a P -semimartingale with decomposition (1) and P, Q are equivalent probability measures, then X is a Q -semimartingale with the decomposition $X_t = X_0 + \tilde{A}_t + \tilde{M}_t$, where

$$\tilde{M}_t = M_t - \int_0^t \frac{1}{Z_s} d[Z, M]_s \quad (12)$$

$Z_t = E_P\left(\frac{dQ}{dP} | \mathcal{F}_t\right)$ and $\tilde{A}_t = X_t - X_0 - \tilde{M}_t$. The latter result is known as *Girsanov's Theorem* (see [6] p. 133).

Furthermore, semimartingales are stable under certain changes of filtration. Let X be a semimartingale for the filtration $\mathbb{F}$. If $\mathbb{G} \subset \mathbb{F}$ is a subfiltration and X is adapted to $\mathbb{G}$, then X is a semimartingale for $\mathbb{G}$ (*Stricker's Theorem*). Semimartingales are also invariant to certain enlargement of filtration. Let $\mathcal{A} \subset \mathcal{F}$ be a collection of events such that $A, B \in \mathcal{A}$, $A \neq B$, implies $A \cap B = \emptyset$. Let $\mathcal{H}_t$ be generated by $\mathcal{F}_t$ and $\mathcal{A}$. Then every $(\mathbb{F}, P)$ -semimartingale is a $(\mathbb{H}, P)$ -semimartingale (*Jacod's Countable Expansion*).

Itô's Formula

Semimartingales are stable under C^2 -transformation. Let $X = (X^1, \dots, X^d)$ be a d -dimensional semimartingale and $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be a function with continuous second-order partial derivatives. Then $f(X)$ is again a semimartingale and the **Itô's Formula** holds:

$$\begin{aligned} f(X_t) - f(X_0) &= \sum_{i=1}^d \int_0^t \frac{\partial f}{\partial x_i}(X_{s-}) dX_s^i \\ &+ \frac{1}{2} \sum_{i,j=1}^d \int_0^t \frac{\partial^2 f}{\partial x_i \partial x_j}(X_{s-}) d[X^i, X^j]_s^c \\ &+ \sum_{0 \leq s \leq t} \left(f(X_s) - f(X_{s-}) \right. \\ &\quad \left. - \sum_{i=1}^d \frac{\partial f}{\partial x_i}(X_{s-}) \Delta X_s^i \right) \end{aligned} \quad (13)$$

One of the most interesting applications of **Itô's formula** is the so-called *Doléans–Dade exponential* (see **Stochastic Exponential**). Let X be a (one-dimensional) semimartingale with $X_0 = 0$. Then there exists a unique semimartingale Z that satisfies the equation $Z_t = 1 + \int_0^t Z_{s-} dX_s$. This solution is denoted by $\mathcal{E}(X)$ (the Doléans–Dade exponential) and is given by

$$\begin{aligned} \mathcal{E}(X)_t = & \exp\left(X_t - \frac{1}{2}[X, X]_t\right) \prod_{0 \leq s \leq t} (1 + \Delta X_s) \\ & \times \exp\left(-\Delta X_s + \frac{1}{2}|\Delta X_s|^2\right) \end{aligned} \quad (14)$$

Moreover, we obtain the identity $\mathcal{E}(X)\mathcal{E}(Y) = \mathcal{E}(X + Y + [X, Y])$.

An important example is $X_t = at + \sigma W_t$, where W denotes the Brownian motion and a, σ are constant. In this case, the continuous solution $\mathcal{E}(X)_t = \exp\left(\left(a - \frac{\sigma^2}{2}\right)t + \sigma W_t\right)$ is known as the *Black–Scholes model*.

Capital Asset Pricing Model

The 1990 Nobel Prize winner William Sharpe [49, 50] introduced one cornerstone of the modern finance theory with his seminal capital asset pricing model (CAPM) for which Black [9], Lintner [35, 36], Mossin [43], and Treynor [54] proposed analogous and extended versions. He then proposed an answer to the financial theory's question about the uncertainty surrounding any investment and any financial asset. Indeed, financial theory raised the question of how risk impacts the fixing of asset prices in the financial market (*see* **Modern Portfolio Theory**), and William Sharpe proposed an explanation of the link prevailing between risky asset prices and market equilibrium. The CAPM therefore proposes a characterization of the link between the risk and return of financial assets, on one side, and market equilibrium, on the other side. This fundamental relationship establishes that the expected excess return of a given risky asset (*see* **Expectations Hypothesis; Risk Premia**) corresponds to the expected market risk premium (i.e., market price of risk) times a constant parameter called *beta* (i.e., a proportionality constant). The beta is a measure of the asset's relative risk and represents the asset price's propensity to move with the market. Indeed, the beta assesses the extent to which the asset's price follows the market trend simultaneously. Namely, the CAPM explains that, on an average basis, the unique source of risk impacting the returns of risky assets comes from the broad financial market to which all the risky assets belong and on which they are all traded. The main result is that the global risk of a given financial asset can be split into two distinct components, namely, a market-based component and a specific component. This specific component vanishes within well-diversified portfolios so that their global risk summarizes to the broad market influence.

Framework and Risk Typology

The CAPM provides a foundation for the theory of market equilibrium, which relies on both the utility theory (*see* **Utility Theory: Historical Perspectives**) and the portfolio selection theory (*see* **Markowitz, Harry**). The main focus consists of analyzing and

understanding the behaviors and transactions of market participants on the financial market. Under this setting, market participants are assumed to act simultaneously so that they can invest their money in only two asset classes, namely, risky assets, which are contingent claims, and nonrisky assets such as the risk-free asset. The confrontation between the supply and demand of financial assets in the market allows, therefore, for establishing an equilibrium price (for each traded asset) once the supply of financial assets satisfies the demand of financial assets. The uncertainty surrounding contingent claims is so that the general equilibrium theory explains risky asset prices by the equality between the supply and demand of financial assets. Under this setting, Sharpe [49, 50] assumes that the returns of contingent claims depend on each other only due to a unique exogenous market factor called the *market portfolio*. The other potential impacting factors are assumed to be random.

Hence, the CAPM results immediately from Markowitz [37, 38] setting since it represents an equilibrium model of financial asset prices (*see* **Markowitz, Harry**). Basically, market participants hold portfolios, which are composed of the risk-free asset and the market portfolio (representing the set of all traded risky assets). The market portfolio is moreover a mean–variance efficient portfolio, which is optimally diversified and satisfies equilibrium conditions (*see* **Efficient Markets Theory: Historical Perspectives; Efficient Market Hypothesis; Risk–Return Analysis**). Consequently, holding a risky asset such as a stock is equivalent to holding a combination of the risk-free asset and the market portfolio, the market portfolio being the unique market factor.

The Capital Asset Pricing Model

Specifically, Sharpe [49, 50] describes the uncertainty underlying contingent claims with a one-factor model—the CAPM. The CAPM illustrates the establishment of financial asset prices under uncertainty and under market equilibrium. Such equilibrium is partial and takes place under a set of restrictive assumptions.

Assumptions

1. Markets are *perfect* and without frictions: no tax, no transaction costs (*see* **Transaction Costs**),

- and no possibility of manipulating asset prices in the market (i.e., perfect market competition).
2. Information is instantaneously and perfectly available in the market so that investors simultaneously access the same information set without any cost.
 3. Market participants invest over *one time period* so that we consider a one-period model setting.
 4. Financial assets are infinitely divisible and liquid.
 5. Lending and borrowing processes apply the risk-free rate (same rate of interest), and there is no short sale constraint.
 6. Asset returns are *normally distributed* so that expected returns and corresponding standard deviations are sufficient to describe the assets' behaviors (i.e., their probability distributions). The Gaussian distribution assumption is equivalent to a quadratic utility setting.
 7. Investors are *risk averse and rational*. Moreover, they seek to maximize the expected utility of their future wealth/of the future value of their investment/portfolio (*see Expected Utility Maximization: Duality Methods; Expected Utility Maximization*; and the two-fund separation theorem of Tobin [52]).
 8. Investors build *homogeneous expectations* about the future variation of interest rates. All the investors build the same forecasts about the expected returns and the variance-covariance matrix of stock returns. Therefore, there is a unique set of optimal portfolios. Basically, investors share the same opportunity sets, which means they consider the same sets of accessible and "interesting" portfolios.
 9. The combination of two distinct and independent risk factors drives the evolution of any risky return over time, namely, the broad financial market and the fundamental/specific features of the asset under consideration. Basically, the risk level embedded in asset returns results from the trade-off between a market risk factor and an idiosyncratic risk factor.

The market risk factor is also called *systematic risk factor* and *nondiversifiable risk factor*. It represents a risk factor, which is common to any traded financial asset. Specifically, the market risk factor represents the global evolution of the financial market and the economy (i.e., trend of the broad market, business cycle), and impacts any risky asset. Indeed,

it characterizes the systematic fluctuations in asset prices, which result from the broad market. In a complementary way, the specific risk factor is also called *idiosyncratic risk factor*, *unsystematic risk factor*, or *diversifiable risk factor*. It represents a component, which is peculiar to each financial asset or to each financial asset class (e.g., small or large caps). This specific component in asset prices has no link with the broad market. Moreover, the systematic risk factor is priced by the market, whereas the idiosyncratic risk factor is not priced by the market. Specifically, market participants ascribe a nonzero expected return to the market risk factor, whereas they ascribe a zero expected return to the specific risk factor. This feature results from the fact that the idiosyncratic risk can easily be mitigated within a well-diversified portfolio, namely, a portfolio with a sufficient number of heterogeneous risky assets so that their respective idiosyncratic risks cancel each other. Thus, a diversified portfolio's global risk (i.e., total variance) results only from the market risk (i.e., systematic risk).

CAPM equation

Under the previous assumptions, the CAPM establishes a linear relationship between a portfolio's expected risk premium and the expected market risk premium as follows:

$$E[R_P] = r_f + \beta_P \times (E[R_M] - r_f) \quad (1)$$

where R_M is the return of the market portfolio; R_P is the return of portfolio P (which may also correspond to a given stock i); r_f is the risk-free interest rate; β_P is the beta of portfolio P ; and $E[R_M] - r_f$ is the market price of risk. The market portfolio M is composed of all the available and traded assets in the market. The weights of market portfolio's components are proportional to their corresponding market capitalization relative to the global broad market capitalization. Therefore, the market portfolio is representative of the broad market evolution and its related systematic risk. Finally, β_P is a systematic risk measure also called *Sharpe coefficient* since it quantifies the sensitivity of portfolio P or stock i to the broad market. Basically, the portfolio's beta is written as

$$\beta_P = \frac{\text{Cov}(R_P, R_M)}{\text{Var}(R_M)} = \frac{\sigma_{PM}}{\sigma_M^2} \quad (2)$$

where $\text{Cov}(R_P, R_M) = \sigma_{PM}$ is the covariance between the portfolio's return and the market return,

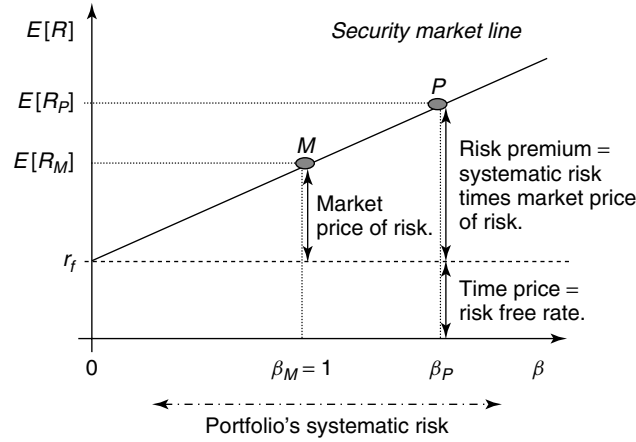

Figure 1 Security market line

and $\text{Var}(R_M) = \sigma^2_M$ is the market return's variance over the investment period. In other words, beta is the risk of covariation between the portfolio's and the market's returns normalized by the market return's variance. Therefore, beta is a relative risk measure. Under the Gaussian return assumption, the standard deviation, or equivalently the variance, is an appropriate risk metric for measuring the dispersion risk of asset returns.

Therefore, under equilibrium, the portfolio's expected return R_P equals the risk-free rate increased by a risk premium. The risk premium is a linear function of the systematic risk measure as represented by the beta and the market price of risk as represented by the expected market risk premium. Such a relationship is qualified as the security market line (SML; see Figure 1). Since idiosyncratic risk can be diversified away, only the systematic risk component in asset returns matters.^a Intuitively, diversified portfolios cannot get rid of their respective dependency to the broad market. From a portfolio management prospect, the CAPM relationship then focuses mainly on diversified portfolios, namely, portfolios or stocks with no idiosyncratic risk.

It then becomes useless to keep any idiosyncratic risk in a given portfolio since such a risk is not priced by the market. The beta parameter becomes subsequently the only means to control the portfolio's risk since the CAPM relationship (1) establishes the premium investors require to bear the portfolio's systematic risk. Indeed, the higher the dependency on the broad financial market is, the greater the risk premium

required by investors becomes. Consequently, the beta parameter allows investors to classify assets as a function of their respective systematic risk level (see Table 1).

Assets with negative beta values are usually specific commodity securities such as gold-linked assets. Moreover, risk-free securities such as cash or Treasury bills, Treasury bonds, or Treasury notes belong to the zero-beta asset class. Risk-free securities are independent from the broad market and exhibit a zero variance, or equivalently a zero standard deviation. However, the class of zero-beta securities includes also risky assets, namely, assets with a nonzero variance, which are not correlated with the market.

Table 1 Systematic risk classification

Beta level	Classification
$\beta > 1$	Offensive, cyclical asset amplifying market variations
$0 < \beta < 1$	Defensive asset absorbing market variations
$\beta = 1$	Market portfolio or asset mimicking market variations
$\beta = 0$	Asset with no market dependency
β lies between -1 and 1	Asset with low systematic risk level
$ \beta $ lies above 1	Asset with a higher risk level than the broad market's risk

Estimation and Usefulness

The CAPM theory gives a partial equilibrium relationship, which is assumed to be stable over time. However, how can we estimate such a linear relationship in practice and how do we estimate a portfolio's beta? How useful is this theory to market participants and investors?

Empirical Estimation

As a first point, under the Gaussian return assumption, beta coefficients can be computed while considering the covariance and variance of asset returns over the one-period investment horizon (see equation (2)). However, this way of computing beta coefficients does not work in a non-Gaussian world. Moreover, beta estimates depend on the selected market index, the studied time window, and the frequency of historical data [8].

As a second point, empirical estimations of the CAPM consider historical data and select a stock market index as a proxy for the CAPM market portfolio. Basically, the CAPM is tested while running two possible types of regressions based on observed asset returns (i.e., past historical data). Therefore, stocks' and portfolios' betas are estimated by regressing past asset returns on past market portfolio returns. We therefore focus on the potential existence of a linear relationship between stock/asset returns and market returns. The first possible estimation method corresponds to the market model regression as follows:

$$R_{it} - r_f = \alpha_i + \beta_i \times (R_{Mt} - r_f) + \varepsilon_{it} \quad (3)$$

where R_{it} is the return of asset i at time t ; R_{Mt} is the market portfolio's return at time t , namely, the systematic risk factor as represented by the chosen market benchmark, which is the unique explanatory factor; r_f is the short-term risk-free rate; ε_{it} is a Gaussian white noise with a zero expectation and a constant variance $\sigma_{\varepsilon_i}^2$; α_i is a constant trend coefficient; and the slope coefficient β_i is simply the beta of asset i . The trend coefficient α_i measures the distance of the asset's average return to the security market line, namely, the propensity of asset i to overperform (i.e., $\alpha_i > 0$) or to underperform (i.e., $\alpha_i < 0$) the broad market. In other words, α_i is the difference between the expected return forecast provided by the security market line and the average return observed on past history. The error term ε_{it} represents the diversifiable/idiosyncratic risk factor

describing the return of asset i . Therefore, R_{Mt} and ε_{it} are assumed to be independent, whereas (ε_{it}) are supposed to be mutually independent. Regression equation (3) is simply the ex-post form of the CAPM relationship, namely, the application of CAPM to past observed data [27].

The second method for estimating CAPM betas is the characteristic line so that we consider the following regression:

$$R_{it} = a_i + b_i \times R_{Mt} + \varepsilon_{it} \quad (4)$$

where a_i and b_i are constant trend and slope regression coefficients, respectively [51]. Moreover, such coefficients have to satisfy the following constraints:

$$\alpha_i = a_i - (1 - b_i) \times r_f \quad (5)$$

$$\beta_i = b_i \quad (6)$$

Regression equations (3) and (4) are only valid under the strong assumptions that α_i and β_i coefficients are stationary over time (e.g., time stability), and that each regression equation is a valid model over each one-period investment horizon.

In practice, the market model (3) is estimated over a two-year window of weekly data, whereas the characteristic line (4) is estimated over a five-year window of monthly data. Basically, the market model and the characteristic line use, as a market proxy, well-chosen stock market indexes such as NYSE index and S&P500 index, respectively, which are adapted to the frequency of the historical data under consideration.

Practical Use

A sound estimation process is very important insofar as the CAPM relationship intends to satisfy investors' needs. From this viewpoint, the main goal of CAPM estimation is first to use past-history beta estimates to forecast future betas. Specifically, the main objective consists of extracting information from past history to predict future betas. However, extrapolating past beta estimates to build future beta values may generate estimation errors resulting from outliers due to firm-specific events or structural changes either in the broad market or in the firm [10].

Second, the CAPM is a benchmark tool helping investors' decision. Specifically, the SML is used to identify overvalued (i.e., above SML) and undervalued (i.e., below SML) stocks under a fundamental

analysis setting. Indeed, investors compare observed stock returns with CAPM required returns and then assess the performance of the securities under consideration. Therefore, the CAPM relationship provides investors with a tool for investment decisions and trading strategies since it provides buy and sell signals, and drives asset allocation across different asset classes.

Third, the CAPM allows for building classical performance measures such as Sharpe ratio (*see Sharpe Ratio*), Treynor index, or Jensen's alpha (*see Style Analysis; Performance Measures*). Finally, the CAPM theory can be transposed to firm valuation insofar as the equilibrium value of the firm is the discounted value of its future expected cash flows. The discounting factor is just mitigated by one identified risk factor affecting equity [20, 29, 30, 47]. According to the theorem proposed by Modigliani and Miller [40–42] (*see Modigliani–Miller Theorem*), the cost of equity capital for an indebted firm corresponds to the risk-free rate increased by an operating risk premium (independent from the firm's debt) times a leverage-specific factor. The firm's risk is therefore measured by the beta of its equity (i.e., equity's systematic risk), which also depends on the beta of the firm's assets and on the firm's leverage. Indeed, the leverage increases the beta of equity in a perfect market and therefore increases the firm's risk, which represents the probability of facing a default situation. However, an optimal capital structure may result from market imperfections such as taxes, agency costs, bankruptcy costs, and information asymmetry among others. For example, there exists a trade-off between the costs incurred by a financial distress (i.e., default) and the potential tax benefits inferred from leverage (i.e., debt). Consequently, applying the CAPM to establish the cost of capital allows for budget planning and capital budgeting insofar as choosing an intelligent debt level allows for maximizing the firm value. Namely, there exists an optimal capital structure.

Limitations and Model Extensions

However, CAPM is only valid under its strong semi-anal assumptions and exhibits a range of shortcomings as reported by Banz [6], for example. However, in practice and in the real financial world, many of these assumptions are violated. As a result, the CAPM suffers from various estimation problems that impact its

efficiency. Indeed, Campbell *et al.* [14] show the poor performance of CAPM over the 1990s investment period in the United States. Such a result does have several possible explanations among which missing explanatory factors, heteroscedasticity in returns or autocorrelation patterns, time-varying or nonstationary CAPM regression estimates. For example, heteroscedastic return features imply that the static estimation of the CAPM is flawed under the classic setting (e.g., ordinary least squares linear regression). One has, therefore, to use appropriate techniques while running the CAPM regression under heteroscedasticity or non-Gaussian stock returns (*see* [7], for example, and *see also Generalized Method of Moments (GMM); GARCH Models*).

General Violations

Basic CAPM assumptions are not satisfied in the market and engender a set of general violations. First, lending and borrowing rates of interest are different in practice. Generally speaking, it is more expensive to borrow money than to lend money in terms of interest rate level. Second, the risk-free rate is not constant over time but one can focus on its arithmetic mean over the one-period investment horizon. Moreover, the choice of the risk-free rate employed in the CAPM has to be balanced with the unit-holding period under consideration. Third, transactions costs are often observed on financial markets and constitute part of the brokers' and dealers' commissions. Fourth, the market benchmark as well as stock returns are often nonnormally distributed and skewed [44]. Indeed, asset returns are skewed, leptokurtic [55], and they exhibit volatility clusters (i.e., time-varying volatility) and long memory patterns [2, 45]. Moreover, the market portfolio is assumed to be composed of all the risky assets available on the financial market so as to represent the portfolio of all the traded securities. Therefore, the broad market proxy or market benchmark should encompass stocks, bonds, human capital, real estate assets, and foreign assets (*see the critique of Roll* [46]). Fifth, financial assets are not infinitely divisible so that only fixed amounts or proportions of shares, stocks, and other traded financial instruments can be bought or sold.

Finally, the static representation of CAPM is at odds with the dynamic investment decision process. This limitation gives birth to multiperiodic extensions of CAPM. Extensions are usually called *intertemporal capital asset pricing models (ICAPMs)*,

and extend the CAPM framework to several unit-holding periods (see [11, 39]).

Trading, Information, and Preferences

Insider trading theory assumes that some market participants hold some private information. Specifically, information asymmetry prevails so that part of existing information is not available to all investors. Under such setting, Easley and O'Hara [22] and Wang [56] show that the trade-off between public and private information affects any firm's cost of capital as well as the related return required by investors. Namely, the existence of private information increases the return required by uninformed investors. Under information asymmetry, market participants exchange indeed information through observed trading prices [18]. Moreover, heterogeneity prevails across investors' preferences. Namely, they exhibit different levels of risk tolerance, which drives their respective investments and behaviors in the financial market. Finally, homogeneous expectations are inconsistent with the symmetry in the motives of transaction underlying any given trade. For a transaction to take place, the buy side has to meet the sell side. Indeed, Anderson *et al.* [4] show that heterogeneous beliefs play a nonnegligible role in asset pricing.

Nonsynchronous Trading

Often, the market factor of risk and stocks are not traded at the same time on the financial market, specifically at the daily frequency level. This stylized fact engenders the so-called nonsynchronous trading problem. When the market portfolio is composed of highly liquid stocks, the nonsynchronism problem is reduced within the portfolio as compared to an individual stock. However, for less liquid stocks or less liquid financial markets, the previous stylized fact becomes an issue under the CAPM estimation setting. To bypass this problem, the asset pricing theory introduces one-lag systematic risk factor(s) as additional explanatory factor(s) to describe asset returns [13, 21, 48].

Missing Factors

The poor explanatory power of the CAPM setting [14] comes from the lack of information describing stock returns in the market among others. The broad market's uncertainty is described by a unique risk

factor: the market portfolio. Indeed, considering the market portfolio as the unique source of systematic risk, or equivalently as the unique systematic risk information source is insufficient. To bypass this shortcoming, a wide academic literature proposes to add complementary factors to the CAPM in order to better forecast stock returns (*see Arbitrage Pricing Theory; Predictability of Asset Prices; Factor Models*). Those missing factors are often qualified as asset pricing anomalies [5, 24, 26, 31]. Namely, the absence of key explanatory factors generates misestimations in computed beta values.

For example, Fama and French [25] propose to consider two additional factors such as the issuing firm's size and book-to-market characteristics. Further, Carhart [16] proposes to add a fourth complementary factor called *momentum*. The stock momentum represents the significance of recent past stock returns on the current observed stock returns. Indeed, investors' sentiment and preferences may explain expected returns to some extent. In this prospect, momentum is important since investors make the difference between poor and high performing stocks over a recent past history. More recently, Li [34] proposed two additional factors to the four previous ones, namely, the earnings-to-price ratio and the share turnover as a liquidity indicator. Indeed, Acharya and Pedersen [1], Brennan and Subrahmanyam [12], Chordia *et al.* [19], and Keene and Peterson [32] underlined the importance of liquidity as an explanatory factor in asset pricing. Basically, the trading activity impacts asset prices since the degree of transactions' fluidity drives the continuity of observed asset prices. In other words, traded volumes impact market prices, and the impact's magnitude depends on the nature of market participants [17].

Time-varying Betas

Some authors like Tofallis [53] questioned the soundness of CAPM while assessing and forecasting stock returns' performance. Indeed, the CAPM relationship is assumed to remain stable over time insofar as it relies on constant beta estimates over each unit-holding period (i.e., reference time window). Such a process assumes implicitly that beta estimates remain stable in the near future so that ex-post beta estimates are good future risk indicators. However, time instability is a key feature of beta estimates. For example,

Gençay *et al.* [28] and Koutmos and Knif [33] support time-varying betas in CAPM estimation.

Moreover, CAPM-type asset pricing models often suffer from error-in-variables problems coupled with time-varying parameters features [15]. To solve such problems, authors like Amman and Verhoeven [3], Ellis [23], and Wang [57] among others advocate using conditional versions of the CAPM. Moreover, Amman and Verhofen [3] and Wang [57] show the efficiency of conditional asset pricing models and exhibit the superior performance of the conditional CAPM setting as compared to other asset pricing models.

End Notes

^aSpecifically, the systematic risk represents that part of returns' global risk/variance, which is common to all traded assets, or equivalently, which results from the broad market's influence.

Arbitrage Pricing Theory

The arbitrage pricing theory (APT) was introduced by Ross [10] as an alternative to the capital asset pricing model (CAPM). The model derives a multibeta representation of expected returns relative to a set of K reference variables under assumptions that may be described roughly as follows:

1. There exists no mean–variance arbitrage.
2. The asset returns follow a K -factor model.
3. The reference variables and the factors are non-trivially correlated.^a

The first assumption implies that there are no portfolios with arbitrarily large expected returns and unit variance. The second one assumes that the returns are a function of K factors common to all assets, and noise term specific to each asset. The third one identifies the sets of reference variables for which the model works.

The model predictions may have approximation errors. However, these errors are small for each portfolio that its weight on each asset is small (a well-diversified portfolio).

Early versions of the model unnecessarily assumed that the factors are equal to the reference variables. The extension of the model to arbitrary sets of reference variables comes at the cost of increasing the bound on the approximation errors by a multiplicative factor. However, when focusing on pricing of only well-diversified portfolios, this seems to be unimportant because each of the approximation error is small and a multiplicative factor does not change much the size of the error.

Factor Representation

Consider a finite sequence of random variables $\{Z_i; i = 1, \dots, N\}$ with finite variances that will be held fixed throughout the article. It is regarded as representing the excess^b returns of a given set of assets (henceforth “assets $i = 1, \dots, N$ ”). Without any further assumptions

$$Z_i = b_{i,0} + \sum_{k=1}^K b_{i,k} f_k + e_i; \quad i = 1, \dots, N$$

where $f_1, \dots, f_K$ are the first K factors in the principal component analysis (PCA) of the sequence

$\{Z_i; i = 1, \dots, N\}$. The $b_{i,k}$ are the factor loadings and the e_i are the residuals from projecting the Z_i on the factors.

The $K + 1$ largest eigenvalue of the covariance matrix of the Z_i , denoted by $\Lambda^2(K)$, is interpreted as a measure of the extent to which our sequence of assets has a K -factor representation. The PCA selects the f_k so that $\Lambda^2(K)$ is minimized. In addition, $\Lambda^2(K)$ is also the largest eigenvalue of the covariance matrix of the e_i .

Diversified Portfolios

Let $w \in R^N$ be a portfolio in assets $i = 1, \dots, N$. Its excess return is

$$Z_w = \sum_{i=1}^N w_i Z_i.$$

Its representation as a linear function of the factors is

$$Z_w = b_{w,0} + \sum_{k=1}^K b_{w,k} f_k + e_w$$

where $b_{w,k} = \sum_{i=1}^N w_i b_{i,k}$ are the factor loadings and $e_w = \sum_{i=1}^N w_i e_i$ is the residual which satisfies

$$\text{Var}[e_w] < \Lambda^2(K) \sum_{i=1}^N w_i^2$$

A portfolio $w = (w_1, \dots)$ is called an (approximate) well-diversified portfolio if

$$\sum_{i=1}^N w_i^2 \approx 0 \quad (1)$$

Intuitively, a well-diversified portfolio is one with a large number of assets that has a small weight in many of them, and, in addition, there is no single asset for which the weight is not small.

The variance of the residual of a well-diversified portfolio is small and thus its excess return is approximately a linear function of the factors; that is,

$$Z_w \approx b_{w,0} + \sum_{k=1}^K b_{w,k} f_k \quad (2)$$

Although $\sum_{i=1}^N w_i^2 \approx 0$, Z_w may not be small. For example, let $w_i = 1/N$, then we have $\sum_{i=1}^N w_i^2 = 1/N$, and $b_{w,k} = (1/N) \sum_{i=1}^N b_{i,k}$

A further discussion on well-diversified portfolios can be found in [4].

Multibeta Representation

Throughout the article we consider a fixed set of K reference variables $\{g_1, \dots, g_K\}$ with respect to which we derive an approximate *multibeta representation* defined as

$$E[Z_i] = \sum_{k=1}^K B_{i,k} \lambda_k + \rho_i \quad (3)$$

where

$$B_{i,k} = \text{Cov}(Z_i, g_k) \quad (4)$$

This means that

$$E[Z_i] \approx \sum_{k=1}^K B_{i,k} \lambda_k \quad (5)$$

where ρ_i is the approximation error in pricing asset i . The sum of the squares of these approximation errors, that is,

$$\sum_{i=1}^N \rho_i^2 = \Omega^2 \quad (6)$$

determines the quality of the approximation.

The APT Bound

Huberman [3] showed that Ω is finite for an infinite sequence of excess returns but did not derive a bound. Such bounds were derived by Chamberlain & Rothschild [1], in the case where the reference variables are the factors and by Reisman [7], in the general case. Reisman showed that

$$\Omega \leq \Lambda S \Phi \Psi V \quad (7)$$

where $\Lambda^2(K)$ is the $K + 1$ largest eigenvalue of the covariance matrix of the Z_i ; S is the lowest upper bound on expected excess return among portfolios with unit variance; $\Phi^2 = 1 - R^2$ of the regression of the tangency portfolio on the reference variables; Ψ is an increasing function of the largest eigenvalue of $(G'G)^{-1}$, where $G = \text{Corr}(f_n, g_m)_{n,m=1,\dots,K}$ is the cross-correlation matrix of the factors and the reference variables; and V^2 is a bound on the variances of the Z_i . See [5, 8] for further details.

What is important about the bound is that neither Φ nor Ψ depends on the number of assets, N . This means that the size of the bound depends on the number of assets N , only through $\Lambda(K)$, S , and V , which may be bounded as this number increases to infinity.

The Pricing Errors

The pricing error of any portfolio w ,

$$\sum_{k=1}^K w_k \rho_k = \rho_w \quad (8)$$

satisfies

$$|\rho_w|^2 \leq \Omega \sum_{i=1}^N w_i^2 \quad (9)$$

Provided Ω is not large and N is large, the pricing error on each well-diversified portfolio is small. For a single asset i , we only get that most of the ρ_i are small. However, for a few of the assets the ρ_i may not be small.

Example

Assume that each Z_i is given by

$$Z_i = a_i + b_i f + e_i$$

where the e_i are mutually uncorrelated and have zero mean, and f has a zero mean and unit variance and is uncorrelated with all the e_i .

The APT implies that every random variable g for which $\text{cov}(g, f)$ is not zero can serve as a reference variable. Thus there exists a constant λ so that

$$E[Z_i] = \text{cov}(Z_i, g) \lambda + \rho_i \text{ for each } i$$

In addition, for each well-diversified portfolio w , we have

$$E[Z_w] \approx \text{cov}(Z_w, g) \lambda$$

In this example, $\Psi = 1/\text{corr}(f, g)^2$; $\Lambda(1)$ and S and Φ may take arbitrary values.

Empirical Studies

Empirical studies attempted to find the sets of reference variables for which the hypothesis that

$$E[Z_i] = \sum_{k=1}^K B_{i,k} \lambda_k$$

cannot be rejected. Roll and Ross [9] identified sets of macroeconomic variables that are believed to be responsible for stock price movements and tested whether they explain expected returns in the major US markets. Trzcinka [13] applied PCA to identify the factors. He showed that a small number of factors

may explain most of the variation of the market. Then he tested the multibeta representation with these factors as reference variables.

Equilibrium APT

The CAPM implies that the market portfolio is mean–variance efficient. If the market portfolio is a well-diversified one, then it is spanned by the factors. In that case, we get that if the reference variables are the factors, then Φ is small, which implies that the approximation error for each asset in the sequence is small. Connor [2] and Wei [14] derived a related result which is called equilibrium APT.

Arbitrage and APT

S measures the extent to which arbitrage in the mean–variance sense exists. It is equal to the maximal expected excess return per unit variance of portfolios in the Z_i . A large S can be interpreted as some form of no arbitrage. However it is not an arbitrage in the standard sense as there are examples in which S is finite and arbitrage exists. See Reisman [6].

Testability

It was pointed out by Shanken [11, 12] that an inequality of the type given in equation (7) is a tautology. That is, it is a mathematical statement and thus cannot be rejected.

Assume that we performed statistical tests that imply that the probability that the bound in equation (7) holds, is small. Then the only explanation can be that it was a bad sample. Since equation (7) is a tautology, there is no other explanation.

Nevertheless, this does not imply that the bound is not useful. The bound translates prior beliefs on the sizes of Λ , S , and Ψ , into a prior belief on a bound on the size of the approximation error of each well-diversified portfolio.

The relationship between the sizes of Λ , S , and Ψ , and the model assumptions is illustrated in the next section.

The APT Assumptions

The model is derived under assumptions on the extent to which there exists

1. a factor structure with K factors;
2. no mean–variance arbitrage;
3. nontrivial correlation between our set of reference variables and the first K factors in the PCA.

The parameters Λ , S , and Ψ are measures of the extent to which each of the above assumptions holds. The larger it is, the larger is the extent to which the related assumption does not hold.

What this says is that the model translates our beliefs on the extent to which the model assumptions hold to a belief on a bound on the size of the approximation errors in pricing well-diversified portfolios.

Summary

The APT implies that each (approximate) well-diversified portfolio is (approximately) priced by a set of K reference variables.

What distinguishes this model from the K -factor CAPM is the set of reference variables that is implied by each of the models.

In the CAPM, the market portfolio is mean–variance efficient and its return must be equal to a linear function of the set of reference variables.

In contrast, in the APT, the reference variables are any set that is nontrivially correlated with the common factors of the returns and it may not span the mean–variance frontier.

End Notes

^aThe cross-correlation matrix is nonsingular.

^bThe excess return is the return minus the risk-free rate.

Efficient Market Hypothesis^a

The topic of capital market efficiency plays a central role in introductory instruction in finance. After investigating the risk–return trade-off and the selection of optimal portfolios, instructors find it natural to go on to raise the question of what information is incorporated in the estimates of risk and expected return that underlie portfolio choices. Information that is “fully reflected” in security prices (and therefore in investors’ estimates of expected return and risk) cannot be used to construct successful trading rules, which are defined as those with an abnormally high expected return for a given risk. In contrast, information that is not fully reflected in security prices can be so used. Students appear to find this material plausible and intuitive, and this is the basis of its appeal. Best of all, the idea of capital market efficiency appears not to depend on the validity of particular models, implying that students can grasp the major ideas without wading through the details of finance models.

However, those who are accustomed to relying on formal models to discipline their thinking find that capital market efficiency has the disadvantage of its advantage: the fact that market efficiency is not grounded in a particular model (unlike, e.g., portfolio theory) means that it is not so easy to determine what efficiency really means. To see this, consider the assertion of Fama [8] that capital market efficiency can only be tested in conjunction with a particular model of returns. This statement implies that there exist two independent sources of restrictions on the data that are being tested jointly: the assumed model and market efficiency. Analysts who are used to deriving all restrictions being tested from the assumed model find this puzzling: what is the additional source of information that is separate from the model?

This question was not addressed clearly in the major expositions of market efficiency offered by its proponents. One way to resolve this ambiguity is to look at the empirical tests that are interpreted as supporting or contradicting market efficiency. Most of the empirical evidence that Fama [7] interpreted as supporting market efficiency is based on a particular model: expected returns conditional on some pre-specified information set are constant. For example, return autocorrelatedness is evidence against market

efficiency only if market efficiency is identified with constancy of expected returns. On this reading, the additional restriction implied by market efficiency might consist of the assumption that investors have rational expectations. The market model explains asset prices based on investors’ subjective perceptions of their environment; the assumption of rational expectations is needed to connect these subjective perceptions with objective correlations. Admittedly, it is pure conjecture to assume that proponents intend this identification of market efficiency with rational expectations—as Berk [1] pointed out, there is no mention of rational expectations in [7, 8].

In many settings, conditional expected returns are constant over time when agents are risk neutral. If agents are risk averse, expected returns will generally differ across securities, as is clear from the capital asset pricing model (*see Capital Asset Pricing Model*), and will change over time according to the realizations of the conditioning variables even in stationary settings [14, 19]. Hence, if investors are risk averse, the assumption of rational expectations will not generally lead to returns that are fair games.

Analysts who understood that constancy of expected returns requires the assumption of risk neutrality (or some other even more extreme assumption, such as that growth rates of gross domestic product are independently and identically distributed over time) were skeptical about the empirical evidence offered in support of market efficiency. From the fact that high-risk assets generate higher average returns than low-risk assets—or from the fact that agents purchase insurance even at actuarially unfavorable prices, or from a variety of other considerations—we know that investors are risk averse. If so, there is no reason to expect that conditional expected returns will be constant.

One piece of evidence offered in the 1970s, which appeared to contradict the consensus in support of market efficiency, had to do with the volatility of security prices and returns. If conditional expected returns are constant, then the volatility of stock prices depends entirely on the volatility of dividends (under some auxiliary assumptions, such as exclusion of bubbles). This observation led LeRoy and Porter [16] and Shiller [23] to suggest that bounds on the volatility of stock prices and returns can be derived from the volatility of dividends. These authors concluded that stock prices appear to be more

volatile than can be justified by the volatility of dividends. This finding corroborated the informal opinion (that was subsequently confirmed by Cutler *et al.* [6]) that large moves in stock prices generally cannot be convincingly associated with contemporaneous news that would materially affect expected future dividends.

Connecting the volatility of stock prices with that of dividends required a number of auxiliary econometric specifications. These were supplied differently by LeRoy–Porter and Shiller. However, both sets of specifications turned out to be controversial (see [9] for a survey of the econometric side of the variance-bounds tests). Some analysts, such as Marsh and Merton [20], concluded that the appearance of excess volatility was exactly what should be expected in an efficient market, although the majority opinion was that resolving the econometric difficulties reduces but does not eliminate the excess volatility [25].

It was understood throughout that the variance bounds were implications of the assumption that expected returns are constant. As noted, this was the same model that was implicitly assumed in the market efficiency tests summarized by Fama. The interest in the variance-bounds tests derived from the fact that the results of the two sets of tests of the same model appeared to be so different. In the late 1980s, there was a growing realization that small but persistent autocorrelations in returns could explain the excess volatility of prices [24]. This connection is particularly easy to understand if we employ the Campbell–Shiller log-linearization. Defining r_{t+1} as the log stock return from t to $t + 1$, p_t as the log stock price at t , and d_t as the log dividend level, we have

$$p_t \cong k + p_{dt} + p_{rt} \quad (1)$$

where p_{dt} and p_{rt} are given by

$$p_{dt} = E_t \left(\sum_{j=1}^{\infty} \rho^j [(1 - \rho) d_{t+j}] \right) \quad (2)$$

and

$$p_{rt} = -E_t \left(\sum_{j=1}^{\infty} \rho^j r_{t+j} \right) \quad (3)$$

(see [2–4]). Here, k and ρ are parameters associated with the log-linearization. Thus p_{dt} and p_{rt} capture price variations induced by expected dividend variations and expected return variations, respectively.

The attractive feature of the log-linearization is that expectations of future dividends and expectations of future returns appear symmetrically and additively in relation (1). Without the log-linearization, dividends would appear in the numerator of the present-value relation and returns in the denominator, rendering the analysis less tractable.

As noted, the market-efficiency tests of Fama and the variance bounds are implications of the hypothesis that p_{rt} is a constant. If p_{rt} is, in fact, random and positively correlated with p_{dt} , then the assumption of constancy of expected returns will bias the implied volatility of p_t downward. Campbell and Shiller found that if averages of future returns are regressed on current stock prices, a significant proportion of the variation can be explained, contradicting the specification that expected returns are constant.

Campbell *et al.* noted that as economists came to understand the connection between return autocorrelatedness and price and return volatility, the variance-bounds results seemed less controversial:

LeRoy and Porter [16] and Shiller [23] started a heated debate in the early 1980s by arguing that stock prices are too volatile to be rational forecasts of future dividends discounted at a constant rate. This controversy has since died down, partly because it is now more clearly understood that a rejection of constant-discount-rate models is not the same as a rejection of Efficient Capital Markets, and partly because regression tests have convinced many financial economists that expected stock returns are time-varying rather than constant ([2] p. 275).

This passage, in implying that the return autocorrelation results provide an explanation for excess stock price volatility, is a bit misleading. The log-linearized present-value relation (1) is not a theoretical model with the potential to explain price volatility. Rather, it is very close to an identity (the only respect in which equation (1) imposes substantive restrictions lies in the assumption that the infinite sums converge; this rules out bubbles). The Campbell–Shiller exercise amounts to decomposing price variation into dividend variation, return variation, and a covariance term and observing that the latter two terms are not negligible quantitatively. This, although useful, is a restatement of the variance-bounds result, not an explanation of it. Explaining excess volatility would involve accounting in economic terms for the fact that expected returns have the time structure that they do. Campbell and Shiller have not done

this—nor has anyone else. LeRoy–Porter’s conclusion from the variance-bounds tests was that we do not understand why asset prices move as they do. That conclusion is no less true now than it was when the variance-bounds results were first reported.

Fama’s assertion that market efficiency is testable, but only in conjunction with a model of market returns, can be given another reading. Rather than identifying market efficiency with the proposition that investors have rational expectations—alternatively, with the decision to model investors as having rational expectations—one can associate market efficiency with the proposition that asset prices behave as one would expect if security markets were entirely frictionless. In such markets, prices respond quickly to information, implying that investors cannot use publicly available information to construct profitable trading rules because that information is reflected in security prices as soon as it becomes available. In contrast, the presence of major frictions in asset markets is held to imply that prices may respond slowly to information. In that case, the frictions prevent investors from exploiting the resulting trading opportunities.

In the foregoing argument, it is presumed that trading frictions and transactions costs are analogous to adjustment costs. In the theory of investment, it is sometimes assumed that investment in capital goods induces costs that motivate firms to change quantities—in this case, physical capital—more slowly than they would otherwise. It appears natural to assume that prices are similar. For example, real estate prices are held to respond slowly to relevant information because the costs implied by the illiquidity of real estate preclude the arbitrages that would otherwise bring about rapid price adjustment.

Recent work on the valuation of assets in the presence of market frictions raises questions as to the appropriateness of the analogy between quantity adjustment and price adjustment. It is correct that, if prices respond slowly to information, investors may be unable to construct the trades that exploit the mispricing because of frictions. This, however, does not establish that markets clear in settings where prices adjust slowly. Equilibrium models that characterize asset prices in the presence of frictions suggest that in equilibrium prices respond quickly to shocks, just as in the absence of frictions. For example, Krainer [11] and Krainer and LeRoy [13] analyzed equilibrium prices of illiquid assets such

as real estate in a model that accounts explicitly for illiquidity in terms of search and matching. In a similar setting, Krainer [12] introduced economy-wide shocks and found that, despite the illiquidity of real estate, prices adjust instantaneously to the shocks, just as in liquid markets.

A similar result was demonstrated by Lim [17]. He considered the determination of asset prices when short sales are restricted. Lintner [18] and Miller [21], among others, proposed that short sale restrictions cause securities to trade at higher prices than they would otherwise. This is held to occur because investors with negative information may be unable to trade based on their information, whereas those with positive information can buy without restriction. Empirical evidence is held to support this result [5, 10, 22]. Lim showed that this outcome will not occur if investors have rational expectations about the extent of short sales restrictions. Under rational expectations, prices in Lim’s model follow a martingale under the natural probabilities (reflecting assumed risk neutrality), just as they would in the absence of short sales restrictions.

These results were derived in settings that imposed strong restrictions, and it is not clear how general they are. However, the preliminary conclusion is that if market efficiency is defined as the absence of frictions, empirical evidence of quick adjustment of prices to information cannot necessarily be interpreted as supporting market efficiency, since that outcome would occur in the presence of frictions.

It could be objected that none of these considerations supports distinguishing between the implications of an asset pricing model and market efficiency, however defined. All testable restrictions are derived from an assumed model; so, the question is, what can be gained by identifying some of these restrictions with something called *market efficiency*? This is particularly debatable, given the ambiguity in the usage of this term now. Berk [1] suggested dropping the term “market efficiency” from financial economics, and this might be the best course.

End Notes

^a. An evaluation of the idea of capital market efficiency has been presented elsewhere [15]. In this essay, repetition of material found there has been avoided as much as possible.

Expectations Hypothesis

If the attractiveness of an economic hypothesis is measured by the number of papers which statistically reject it, the expectations theory of the term structure is a knockout [43].

The term *expectations hypothesis (EH)* stands for numerous statements that link yields, returns on bonds, and forward rates of different maturities and periods. The EH has been the basis of empirical and theoretical work in fixed income following the work of Macaulay [54]. These hypotheses were developed for understanding the returns and yields on long- *versus* short-term bonds and the time series movements of the term structure. The literature distinguishes between the *pure expectations hypothesis (PEH)*, which postulates that (i) expected excess returns on long-term over short-term bonds are zero, (ii) yield term premia are zero, or (iii) forward term premia are zero, from the EH, which postulates that (i) expected excess returns are constant over time, (ii) yield term premia are constant, or (iii) forward term premia are constant over time.

We review the literature related to the EH. We present the different forms of both the PEH and the less strong EH. We show that their mathematical expressions depend on the researchers' choice of model—continuous time *versus* discrete time—and their choice of frequency of compounding returns—continuous (log-return) *versus* discrete (simple return). Depending on these choices, we may or may not have equivalence among the several forms of the (pure) EH. In addition, we examine which of the statements can be derived from a no-arbitrage general equilibrium model. Lastly, we present empirical evidence against the EH mainly from the US data, and the less strong rejection of the hypotheses when using non-US data.

Notation

To formulate the different forms of the EH, we need to introduce the basic fixed income assets and concepts associated with them. Even though all the empirical research is done using discrete time models, the theoretical literature predominantly uses continuous time models mainly for tractability

and simplicity reasons. In comparing the expected returns on two bonds of different maturities, however, the returns may be compounded in any of four natural ways: continuously, to the shorter bond's maturity, to the longer bond's maturity, or to the nearest available future date. For these reasons, in the following, we introduce notation that is flexible enough to accommodate the description of discrete as well as continuous time models and all possible ways that compounding may take place.

A *zero-coupon bond* or *discount bond*—the simplest fixed income security—promises a single fixed payment at a specified date in the future known as *maturity date*. The size of this payment is called *face value* of the bond. Example of such securities is the Treasury bills, which are bonds issued by the US government with maturities up to a year.

We denote the price of a zero-coupon bond that matures $\tau \in \mathbb{R}^+$ periods from now and pays 1 unit at maturity as $P_t^{(\tau)}$. Call the yield to maturity—compounded once per period—for this zero-coupon bond as $Y_t^{(\tau)}$. Then prices and yields are connected through the following equation:

$$P_t^{(\tau)} = \frac{1}{(1 + Y_t^{(\tau)})^\tau} \quad (1)$$

It is common in the empirical finance literature to work with log or continuously compounded variables. This has the usual advantage of linearizing exponential affine equations that arise frequently in asset pricing and of defining comparable yield values independent of the remaining horizon value τ . Using lowercase letters for logs, the relationship between log yield and log price is

$$y_t^{(\tau)} = -\frac{P_t^{(\tau)}}{\tau} \quad (2)$$

The collection of all these yields for different maturities is called the *zero term structure of interest rates*. Buying this bond at time t and reselling it at time $t + s$ generate a holding period return of

$$R_{t \rightarrow t+s}^{(\tau)} = \frac{P_{t+s}^{(\tau-s)}}{P_t^{(\tau)}} = \frac{(1 + Y_t^{(\tau)})^\tau}{(1 + Y_{t+s}^{(\tau-s)})^{\tau-s}} \quad (3)$$

and a log holding period return of

$$\begin{aligned} r_{t \rightarrow t+s}^{(\tau)} &= p_{t+s}^{(\tau-s)} - p_t^{(\tau)} \\ &= s y_t^{(\tau)} - (\tau - s)(y_{t+s}^{(\tau-s)} - y_t^{(\tau)}) \end{aligned} \quad (4)$$

Clearly, the holding period s cannot exceed the time to maturity τ , $s \leq \tau$. The above equation shows that the holding period return on a zero-coupon bond is not known at time t unless the holding period coincides with the lifetime of the bond. In this case, the holding period return is the yield to maturity. Otherwise, the return is a random variable that depends on the future evolution of yields.

Even though returns are unknown, bonds can be combined to guarantee a fixed interest rate on an investment to be made in the future; the interest rate on this investment is called a *forward rate*. The forward and log forward rates guaranteed at time t for an investment made at time $t + s$ until time $t + \tau$ where $s \leq \tau$ are given as

$$1 + F_t^{(s,\tau)} = \frac{1}{\tau - s} \frac{1}{(P_t^{(\tau)}/P_t^{(s)})} = \frac{1}{\tau - s} \frac{(1 + Y_t^{(\tau)})^\tau}{(1 + Y_t^{(s)})^s} \quad (5)$$

$$f_t^{(s,\tau)} = \frac{P_t^{(s)} - P_t^{(\tau)}}{\tau - s} = y_t^{(s)} + \frac{\tau}{\tau - s} (y_t^{(\tau)} - y_t^{(s)}) \quad (6)$$

Finally, the short-term interest rate is the limit of yields to maturity as maturity approaches, $r_t = \lim_{\tau \downarrow 0} y_t^{(\tau)}$.

Bond Pricing

Bonds are usually priced with the use of the so-called *risk-neutral probability measure* $\mathbb{Q}$, which is equivalent to the *true* or *physical* or *data-generating* measure $\mathbb{P}$.^a The pricing under $\mathbb{P}$ is done with the use of a pricing kernel M , which is the result of the no-arbitrage assumption. For an asset that promises payoff $S(T)$ at time T , its price now at time t is given by the expected discounted cash flows equation:

$$S(t) = \mathbb{E}_t^{\mathbb{P}} \left[\frac{M(T)}{M(t)} S(T) \right] \quad (7)$$

It can be shown that given the shocks of the economy $dz(t)$, M takes the following form:

$$\frac{dM(t)}{M(t)} = -r(t) dt - \Lambda(t)^\top dz(t) \quad (8)$$

and the two measures $\mathbb{P}$ and $\mathbb{Q}(\Lambda)$ are connected through the Radon–Nikodym derivative

$$\frac{d\mathbb{Q}(\Lambda)}{d\mathbb{P}} = \xi_T^\Lambda = \exp \left(-\frac{1}{2} \int_0^T \Lambda(s)^\top \Lambda(s) ds - \int_0^T \Lambda(s) ds \right) \quad (9)$$

This gives rise to the following pricing equation under both measures:

$$S(t) = \mathbb{E}_t^{\mathbb{P}} \left[\frac{M(T)}{M(t)} S(T) \right] = \mathbb{E}_t^{\mathbb{Q}} \left[e^{-\int_t^T r(s) ds} S(T) \right] \quad (10)$$

Easy manipulations of the above equation can prove that under $\mathbb{Q}$, the instantaneous expected returns for all assets are equal to the risk-free rate. For this reason, the measure $\mathbb{Q}$ is also called the *risk-neutral measure*. Specializing the above equation for a zero-coupon bond that matures at time $t + \tau$ and promises a payoff of \$1 gives

$$P_t^{(\tau)} = \mathbb{E}_t^{\mathbb{P}} \left[\frac{M(T)}{M(t)} \right] = \mathbb{E}_t^{\mathbb{Q}} \left[e^{-\int_t^T r(s) ds} \right] \quad (11)$$

From the above pricing equations, we observe that the key variables that govern the bond prices dynamics are (i) the interest rate $r(t)$ and (ii) the prices of risk $\Lambda(t)$. Different assumptions about the functional form of these variables imply different data-generating processes for bond yields. A large part of the current fixed income literature is devoted to studying these different models and the goodness of fitting the raw bond yield data crosssectionally and in time series. We examine below the features of the most representative bond pricing models.

The Expectations Hypothesis

The term *expectations hypothesis* stands for numerous statements that link yields, returns on bonds, and forward rates of different maturities and periods. It is important to note that initially, starting with Hicks [49], Lutz [53], and Macaulay [54], these statements were not formally derived from any fully specified equilibrium model, but rather merely hypothesized. For this reason, the term *expectations hypothesis* is not associated with only one mathematical statement.

These hypotheses were developed for understanding the returns and yields on long- *versus* short-term bonds, and the time series movements of the term structure. Later, researchers developed theoretical models that give rise to some of the hypothesized equations associated with the EH [20, 21, 27, 57].

The literature distinguishes between the PEH, which postulates that (i) expected excess returns on long-term over short-term bonds are zero, (ii) yield term premia are zero, or that (iii) forward term premia are zero, from the EH, which postulates that (i) expected excess returns are constant over time, (ii) yield term premia are constant, or (iii) forward term premia are constant over time. In the following, all the forms of the PEH in discrete time with discrete and continuous compounding and in continuous time (continuous compounding) are presented. We will see that the PEH expressions derived in all these models are not equivalent across models as well as within each model.

Pure Expectations Hypothesis in Discrete Time

Discrete Compounding

The first form of the PEH equates the expected returns on one-period (short-term) and n -period (long-term) bonds, or equivalently, expected excess returns on long-term over short-term bonds are zero:

$$\begin{aligned} (1 + Y_t^{(1)}) &= \mathbb{E}_t^{\mathbb{P}} [1 + R_{t \rightarrow t+1}^{(n)}] \\ &= (1 + Y_t^{(n)})^n \cdot \mathbb{E}_t^{\mathbb{P}} \left[(1 + Y_{t+1}^{(n-1)})^{-n+1} \right] \end{aligned} \quad (12)$$

The second form of the PEH equates the n -period expected returns on the one-period and n -period bonds, or equivalently, yield term premia are zero^b:

$$\begin{aligned} (1 + Y_t^{(n)})^n &= \mathbb{E}_t^{\mathbb{P}} \left[(1 + Y_t^{(1)}) (1 + Y_{t+1}^{(1)}) \right. \\ &\quad \left. \cdots (1 + Y_{t+n-1}^{(1)}) \right] \end{aligned} \quad (13)$$

The third form of the PEH equates the expected future one-period spot rate with the current forward rate

of that future period, or equivalently, forward term premia are zero^c:

$$1 + F_t^{(n-1,n)} = \frac{(1 + Y_t^{(n)})^n}{(1 + Y_t^{(n-1)})^{n-1}} = \mathbb{E}_t^{\mathbb{P}} [1 + Y_{t+n-1}^{(1)}] \quad (14)$$

The last form of the PEH equates the n -period bond return with the one-period bond and $n - 1$ period bond:

$$(1 + Y_t^{(n)})^n = (1 + Y_t^{(1)}) \mathbb{E}_t^{\mathbb{P}} \left[(1 + Y_{t+1}^{(n-1)})^{n-1} \right] \quad (15)$$

Even though the above expressions describe different forms of the PEH, they are not mutually equivalent. Assuming that the above expressions are true for all t and n , it can be shown that (i) equation (13) is equivalent to equation (15), (ii) equation (14) implies equation (13) (therefore equation (15)), but the opposite is not true unless we make the additional assumption that $(1 + Y_{t+j}^{(1)})_{j=1}^{\infty}$ are uncorrelated with each other, and (iii) equations (12) and (15) are inconsistent, because the expected value of the inverse of a random variable is not in general equal to the inverse of its expected value.

To summarize, the PEH cannot hold in both its one-period form and its n -period form, and, essentially there are three different (competing) forms of the PEH in discrete time, the excess return expression (12), the yield premia expression (13), and the forward premia expression (14).

Imposing more structure in the term structure model by assuming that the interest rate is lognormal and homoscedastic, we can quantify the effect of Jensen's inequality. Under this additional assumption, the excess one-period bond returns under the different hypotheses can be shown to be of $\frac{1}{2} \text{Var}[r_{t \rightarrow t+1}^{(n)} - y_t^{(1)}]$ order. Therefore, the difference between the one-period excess bond returns of different PEH forms is $\text{Var}[r_{t \rightarrow t+1}^{(n)} - y_t^{(1)}]$. Using sample means and standard deviations, we can get an estimate and a standard error of the above quantity. This magnitude is very small for short-term bonds and becomes significant only for long-term bonds; hence, the differences between different forms of the PEH are small except for very long term zero-coupon bonds. Thus, the data reject all forms of the PEH at the short end, but reject no forms of the PEH at the long end of the

term structure. In this sense, the distinction between the different forms of the PEH is not critical for evaluating this hypothesis.

Continuous Compounding

Most empirical research, though, uses neither of the above PEH forms, but a log form of them. Once the PEH is formulated in logs, all the forms of the PEH become equivalent. Using log returns, the counterparts of equations (12), (13), and (14) are

$$y_t^{(1)} = \mathbb{E}_t^{\mathbb{P}}[r_{t \rightarrow t+1}^{(n)}] \quad (16)$$

$$y_t^{(n)} = (1/n) \sum_{i=0}^{n-1} \mathbb{E}_t^{\mathbb{P}}[y_{t+i}^{(1)}] \quad (17)$$

$$f_t^{(\tau-1, \tau)} = \mathbb{E}_t^{\mathbb{P}}[y_{t+\tau-1}^{(1)}] \quad (18)$$

The empirical literature uses equations (17) and (18) in order to construct two related notions of term premia that have played a prominent role in the literature of expected bond returns: the yield premium,

$$c_t^{(n)} \equiv y_t^{(n)} - \frac{1}{n} \sum_{i=0}^{n-1} \mathbb{E}_t^{\mathbb{P}}[y_{t+i}^{(1)}] \quad (19)$$

and the forward term premium,

$$p_t^{(n)} \equiv f_t^{(n, n+1)} - \mathbb{E}_t^{\mathbb{P}}[y_{t+n}^{(1)}]. \quad (20)$$

Derivations of PEH- and EH-tested formulas follow below.

Pure Expectations Hypothesis in Continuous Time

Cox *et al.* [27] restate the PEH forms in continuous time and prove that the different forms are incompatible. The equivalent of expression (12) in continuous time is created by assuming that the holding period is the shortest possible, that is, infinitesimal. In this case, the PEH takes the following form:

$$\frac{\mathbb{E}_t^{\mathbb{P}}[dP_t^{(\tau)}]}{P_t^{(\tau)}} = r(t) dt \quad (21)$$

This expression states that all bonds have the same expected infinitesimal return, equal to the short-term interest rate. However, the above expression is

also known to hold under $\mathbb{Q}$; under the risk-neutral measure, all assets have the same expected return, equal to the risk-free rate. This implies that this form of the PEH postulates that $\mathbb{P} = \mathbb{Q}$. The expression's (13) continuous time equivalent is

$$\frac{1}{P_t^{(\tau)}} = \mathbb{E}_t^{\mathbb{P}} \left[e^{\int_t^{t+\tau} r(s) ds} \right] \quad (22)$$

This statement equates the guaranteed return from holding any zero-coupon bond to maturity with the total return expected from rolling over a series of short-term period bonds. The continuous time equivalent of equation (14) is

$$\frac{-\partial P_t^{(\tau)} / \partial \tau}{P_t^{(\tau)}} = \mathbb{E}_t^{\mathbb{P}}[r(t + \tau)] \quad (23)$$

The left-hand side of the equation is the current infinitesimal forward rate at time $t + \tau$, and the right-hand side is the expected future spot rate at $t + \tau$. Integrating the last equation and applying the boundary condition $P_t^{(0)} = 1$ gives

$$-\ln[P_t^{(\tau)}] = \int_t^{t+\tau} \mathbb{E}_t^{\mathbb{P}}[r(s)] ds \quad (24)$$

Formulating the PEH in continuous time makes the pairwise incompatibility of equations (21), (22), and (24) transparent. If we define the random variable $\tilde{X} \equiv \exp\left(-\int_t^{t+\tau} r(s) ds\right)$, then these equations can be rewritten as

$$P = \mathbb{E}_t^{\mathbb{P}}[\tilde{X}] \quad (25)$$

$$P^{-1} = \mathbb{E}_t^{\mathbb{P}}[\tilde{X}^{-1}] \quad (26)$$

$$\ln(P) = \mathbb{E}_t^{\mathbb{P}}[\ln \tilde{X}] \quad (27)$$

By invoking Jensen's inequality, one can show that the yields to maturity implied from equations (21), (22), and (24) satisfy the relationship (with some abuse of notation):

$$y_t^{(\tau)(21)} \leq y_t^{(\tau)(22)} \leq y_t^{(\tau)(24)} \quad (28)$$

In this model, it is also easy to see that the expected excess returns are positive in all hypotheses except in equation (21).

Perhaps the most impacting result of Cox *et al.* [27] is the characterization of the PEH forms that can be the result of a (no-arbitrage) equilibrium model.

They examine whether there exist pricing kernels (i.e., prices of risk) that can satisfy the resulting pricing PDE in the economy and at the same time satisfy the form of the PEH under examination. They conclude that only equation (21) can be sustained by an equilibrium model. By definition, equation (21) implies that $\mathbb{Q} = \mathbb{P}$; therefore, selecting $\Lambda(t) = \mathbf{0}$ gives rise to a valid pricing kernel. Cox *et al.* [27] prove that the other forms do not give rise to a valid pricing kernel. However, McCulloch [57] later showed that their claim is incorrect. Working in generalizing a preexisting discrete time model to continuous time, he shows that there exists an equilibrium economy that also gives rise to equation (23).

Expectation Hypothesis

As described above, the difference between the EH and the PEH is that the term premia under the PEH are assumed to be zero, whereas under the EH they are assumed to be constant. Therefore, to formulate the different forms of the EH we need to add in each form of the PEH a constant term that depends only upon the remaining time to maturity of the corresponding bond considered in each form of the EH.

Even though the different forms of the PEH are generally incompatible, Campbell [21] showed that the different forms of the EH *are not* incompatible and he derived a general equilibrium model that sustained several forms of the EH at the same time. His model is set up in continuous time. In addition, special cases of the models examined in [16] and [47] provide equilibrium models that give rise to constant term premia [36].

Next, we show the most commonly tested equations of the EH in the literature.

Tests of the Expectations Hypothesis

The EH has been under scrutiny at least since the work of Macaulay [54]. In this study, Macaulay emphasizes the low (given the EH is true) correlation between forward rates and subsequent spot rates. Since then, the EH has been tested in hundreds of studies, and in all of them—with only few exceptions—has been rejected. Some of the early papers that test the EH are those of Sutch [74], Shiller [69, 70, 71], Modigliani and Shiller [59], Sargent [67, 68].

Fama [39, 40] and Fama and Bliss [41] also present challenges of the EH where they find evidence of rich patterns of variation in expected returns across time and maturities. Keim and Stambaugh [50], Fama and French [42], and Campbell and Ammer [23] show that yield spreads help to forecast excess return on bonds as well as on other long-term assets.

Perhaps the most widely cited tests of the EH are the Campbell and Shiller [24] regressions based on the equations:

$$\mathbb{E}_t^{\mathbb{P}} \left[y_{t+m}^{(n-m)} - y_t^{(n)} \right] = \alpha_{nm} + \frac{m}{n-m} (y_t^{(n)} - y_t^{(m)}) \quad (29)$$

which are a more general form of the regressions in [30] based on the following equations:

$$\mathbb{E}_t^{\mathbb{P}} \left[y_{t+1}^{(n-1)} - y_t^{(n)} \right] = \alpha_{n1} + \frac{1}{n-1} (y_t^{(n)} - r_t) \quad (30)$$

that are used to assess the goodness of fit of the different term structure models. The derivations of the above equations are shown in detail in the above-mentioned papers and in [73]. In short, from equation (4) we have that the one-period excess bond continuously compounded return is equal to

$$\begin{aligned} \mathbb{E}_t^{\mathbb{P}} \left[r_{t \rightarrow t+1}^{(n)} - r_t \right] &= -(n-1) \mathbb{E}_t^{\mathbb{P}} \left[y_{t+1}^{(n-1)} - y_t^{(n)} \right] \\ &\quad + (y_t^{(n)} - r_t) \end{aligned} \quad (31)$$

and, it can also be shown that it is equal to

$$\begin{aligned} \mathbb{E}_t^{\mathbb{P}} \left[r_{t \rightarrow t+1}^{(n)} - r_t \right] &= -(n-1) \mathbb{E}_t^{\mathbb{P}} \left[c_{t+1}^{(n-1)} - c_t^{(n)} \right] \\ &\quad + p_t^{(n-1)} \end{aligned} \quad (32)$$

where $c_t^{(n)}$ and $p_t^{(n)}$ are the yield and forward premia defined in equations (19) and (20), respectively. The last expression implies that if the PEH holds (i.e., $c_t^{(n)} = 0$, $p_t^{(n)} = 0$) then the expected excess returns are zero, whereas if the EH holds (i.e., $c_t^{(n)} = c(n)$, $p_t^{(n)} = p(n)$), then the expected excess returns are constants that depend on the time to maturity n . Combining equations (31) and (32) gives rise to equation (30), the well-known LPY regressions of Dai and Singleton [30].

Campbell and Shiller [24] and Dai and Singleton [30], among others, document the failure of both the

regressions (31) and (32), which are true under the EH. According to these equations, the coefficients of the nonconstant terms when regressing $y_{t+m}^{(n-m)} - y_t^{(n)}$ onto $\frac{m}{n-m}(y_t^{(n)} - y_t^{(m)})$, or $\frac{1}{n-1}(y_t^{(n)} - r_t)$ if $m = 1$, should be equal to unity. Not only are the estimated coefficients not unity but also they are often statistically significantly negative, particularly for large n . This means that the EH fails more significantly for long-term bonds. The intuition of the EH is that increases in the slope of term structure ($y_t^{(n)} - r_t$) reflect expectations of rising future short spot rates. For the “buy an n -period bond and hold it to maturity” investment strategy to match, on average, the returns from rolling over short rates in a rising short rate environment, the price of the long bond should decrease such that the yield increases ($y_{t+1}^{(n-1)} > y_t^{(n)}$). The regression results suggest that the slope of the yield curve does not even forecast correctly the direction of the changes in the long-bond yields. The underreaction of long rates to spread term changes has also been the study in [56]. Elaborating and further documenting this underreaction, Campbell [22] finds that yield spreads do not forecast short-run changes in long yields (against EH) but do forecast long-run changes in short yields (consistent with EH).

Backus *et al.* [7] tested the EH by running regressions based on analogous equations for the forward rates:

$$\mathbb{E}_t^{\mathbb{P}} \left[f_{t+1}^{(n-1,n)} - r_t \right] = \alpha + (f_t^{(n-1,n)} - r_t) \quad (33)$$

They also find that the regression coefficients of $(f_t^{(n-1,n)} - r_t)$ are not unity as the null hypothesis sets, but slightly less than one and significantly different than one. They also show that the small differences of the estimated coefficients with unity in the above regressions do not constitute separate or weaker findings against the EH than the deviations of the Campbell–Shiller coefficients from unity, but are actually the same. They constructed a one-factor model and showed that the small differences in the coefficients of the Backus *et al.* [7] regressions from their null value translate into large negative values for the Campbell–Shiller coefficients.

Similar to the above forward regressions are the forward term regressions tested in [43, 72] Shiller *et al.* [72] use a log-linearized model [70, 71] that allows them to test several models of the EH without having to use discount rates (which are

easily available for maturities up to a year, but for longer maturities the rates have to be constructed using spline methods) but with the use of the easily observable coupon-bond yields. One of their regressions is based on the EH equation:

$$\mathbb{E}_t^{\mathbb{P}} \left[y_{t+m}^{(n-m)} - y_t^{(m)} \right] = \alpha_{n,m} + (f_t^{(m,n)} - y_t^{(m)}) \quad (34)$$

Using coupon-bond yields does not change the results that future bond yield changes cannot be predicted by the current term spread of forward spread. Still, even the direction cannot be predicted correctly. They suggest time-varying risk premia as a plausible solution to the failure of the EH. Froot [43] also tests the same equation trying to understand whether its failure is the result of time varying term premia or that expected future spot rates under- or overreact to changes in short rates. He finds that for short maturities its failure is due to variation in term premia, but this is not true for long maturities.

A recent paper that has received a lot of attention is Cochrane and Piazzesi [26]. Cochrane and Piazzesi [26] have revisited the forecasting regressions of Fama and Bliss using the term structure of forward rates instead of a single forward rate. Their most notable finding is that the coefficients from regressing excess bond returns over one year onto the one year forward rates for the next five years exhibit a tentlike shape for all maturity bonds. The tentlike shape similarities for all bond maturities suggest that a single common factor may be underlying the predictability of excess bond returns for all maturities. Another very interesting fact in [26] is the high R^2 s generated in the above regressions. The R^2 s range between 36% and 39%. This is substantially more predictability than in [41] using a single forward factor.

A series of other papers have also examined alternative reasons for the failure of the EH: Mankiew and Miron [55] find that interest rate movements were more predictable before the founding of the Federal Reserve in 1913, and the downward bias appears to be smaller in that period. Campbell and Ammer [23] emphasize that long-term bond yields vary primarily in response to changing expected inflation. Rudebusch [65] argues that contemporary Federal Reserve operating procedures lead to predictable interest rate movements in the very short run and the very long run, but tend to smooth away predictable movements in the medium run. Balduzzi *et al.* [8]

argue that spreads between short-term rates and the overnight federal reserve funds rate are mainly driven by expectations of changes in the target, and not by the transitory dynamics of the overnight rate around the target. Hence, the bias in tests of the EH that they document can be mainly attributed to the erroneous anticipation of future changes in monetary policy.

Several studies have examined the small-sample bias of the regression coefficients. Bekaert and Hodrick [10] argue that the past use of large sample critical regions, instead of their small-sample counterparts, may have overstated the evidence against the expectations theory. They find that the evidence against the EH for these interest rates and exchange rates is much less strong than under asymptotic inference. Other studies, though, such as Backus *et al.* [7] and Bekaert, Hodrick, and Marshall [11], find that the small-sample properties of the regressions like the ones shown in this article are actually biased upward; this means the *true* Campbell–Shiller coefficients are more negative than the ones estimated in the regressions, heightening the puzzle related with the failure of the EH.

Researchers have also looked at the validity of the EH outside the United States. The tendency in these studies is to find Campbell–Shiller coefficients that are less than zero but less negative than the US data results. Some of those studies that are done primarily for European countries and show mixed results are Bekaert and Hodrick [10], Boero and Torricelli [14], Evans [37], Gerlach and Smets [44], Hardouvelis [48], Kugler [51].

Conclusion

The EH constitutes several hypotheses that were generated to understand bond returns and their yields through the help of other maturity bond returns or investment strategies and forward rates. We showed that these hypotheses can be formulated in many different ways and using different models (continuous time *vs* discrete and continuous compounding *vs* discrete). The different hypotheses are not equivalent. Therefore to test the validity of the EH numerous different expressions have to be tested.

The consensus is that the EH fails in the US data. Its failure, though, is less strong or mixed for the non-US data. Researchers challenging and

trying to understand the failure of the EH have hinted on different reasons that may give rise to time-varying expected excess returns on bonds. Even though the understanding of the failure of the EH is not complete, part of the literature is devoted to creating models that better capture this failure and that better replicate the data.

In this strand we can put the papers of reduced form (affine or nonaffine, with macro or without macrovariables) term structure models, such as Ahn *et al.* [1], Ang and Bekaert [2], Bansal and Zhou [9], Bikbov and Chernov [12, 13], Buraschi *et al.* [17], Dai and Singleton [29, 30, 32], Diebold *et al.* [33], Duarte [34], Evans [38], Leippold and Wu [52], and Naik and Lee [59], and those of the structural form models with or without macrovariables, such as, Ang *et al.* [3, 6], Ang and Piazzesi [4, 5], Brandt and Wang [15], Buraschi and Jiltsov [18, 19], Dai [28], Greenwood and Vayanos [45], Guibaud *et al.* [46], Piazzesi [62], Piazzesi and Schneider [63], Rudebusch and Wu [65, 66], Vayanos and Vila [75], and Wachter [76].

Stochastic Discount Factors

Economic agents make investment decisions within active and liquid financial markets. Capital is allocated today in exchange for some future income stream. If there is no uncertainty regarding the future payoff of an investment opportunity, the yield that will be asked on the investment will equal the risk-free interest rate prevailing for the time period covering the time of investment until the time of the payoff. However, in the presence of any payoff uncertainty at the time of undertaking an investment venture, economic agents will typically ask for *risk compensation*, and thus for some *investment-specific* yield, which will discount the expected future payoff stream. The yields that particular agents ask for depend both on their statistical views on possible future outcomes, as well as their attitudes toward risk.

Yields vary across different investment opportunities and their interrelations are difficult to explain. For the *same* agent, a different discounting factor has to be used for every separate valuation occasion. If, however, one is ready to accept discounting that varies *randomly* with the possible outcomes, and therefore accepts the concept of a *stochastic* discount factor, then a very economically consistent theory can be developed. Asset valuation becomes a matter of randomly discounting payoffs under different states of nature and weighing them according to the agent's probability structure. The advantages of this approach are obvious, since a *single* discounting mechanism suffices to describe how *any* asset is priced by the agent.

We discuss the theory of stochastic discount factors first in a discrete-time, finite state space and then in the more practical case of Itô-process models.

Stochastic Discount Factors in Discrete Probability Spaces

We start by introducing all relevant ideas in a very simple one-time-period framework and finite states of the world. There are plenty of textbooks with vast exposition on these and other related themes (e.g., [1] or the first chapters of [9]—see also [5] for the general state-space case).

The Setup

Consider a very simplistic example of an economy, where there are only two dates of interest, represented by times $t = 0$ (today) and $t = T$ (the financial-planning horizon). There are several states of nature possible at time T and, for the time being, these are represented as a *finite* set Ω . Only one $\omega \in \Omega$ will be revealed at time T , but this is not known in advance today.

In the market, there is a *baseline* asset with a price process $S^0 = (S^0_t)_{t=0,T}$. Here, S^0_0 is a strictly positive constant and $S^0_T(\omega) > 0$ for all $\omega \in \Omega$. The process $\beta := S^0_0/S^0_T$ is called the *deflator*. It is customary to regard this baseline asset as *riskless*, providing a simple annualized interest rate $r \in \mathbb{R}_+$ for investment from today to time T ; in this case, $S^0_0 = 1$ and $S^0_T = 1 + rT$. This viewpoint is *not* adapted here, since it is unnecessary.

Together with the baseline asset, there exist d other liquid *traded* assets whose prices S^i_t , $i = 1, \dots, d$ today are known constants, but the prices S^i_T , $i = 1, \dots, d$, at day T depend on the outcome $\omega \in \Omega$, that is, they are random variables.

Agent Portfolio Selection via Expected Utility Maximization

Consider an economic agent in the market as described above. Faced with inherent uncertainty, the agent postulates some likelihood on the possible outcomes, modeled via a *probability measure* $\mathbb{P} : \Omega \mapsto [0, 1]$ with $\sum_{\omega \in \Omega} \mathbb{P}[\omega] = 1$. This gives rise to a probability $\mathbb{P}$ on the subsets of Ω defined via $\mathbb{P}[A] = \sum_{\omega \in A} \mathbb{P}(\omega)$ for all $A \subseteq \Omega$. This probability can either be *subjective*, that is, coming from views that are agent specific, or *historical*, that is, arising from statistical considerations via some estimation procedure.

Economic agents act in the market and optimally invest to maximize their satisfaction. Each agent has some *preference structure* on the possible future random payoffs that is represented here via the *expected utility* paradigm.^a There exists a *continuously differentiable*, *increasing*, and *strictly concave* function $U : \mathbb{R} \mapsto \mathbb{R}$, such that the agent will prefer a random payoff $\xi : \Omega \mapsto \mathbb{R}$ from another random payoff $\zeta : \Omega \mapsto \mathbb{R}$ at time T if and only if $\mathbb{E}^{\mathbb{P}}[U(\xi)] \leq \mathbb{E}^{\mathbb{P}}[U(\zeta)]$, where $\mathbb{E}^{\mathbb{P}}$ denotes expectation with respect to the probability $\mathbb{P}$.

Starting with capital $x \in \mathbb{R}$, an economic agent chooses at day zero a strategy $\theta \equiv (\theta^1, \dots, \theta^d) \in \mathbb{R}^d$, where θ^j denotes the units from the j th asset held in the portfolio. What remains, $x - \sum_{i=1}^d \theta^i S_0^i$, is invested in the baseline asset. If $X^{(x, \theta)}$ is the wealth generated starting from capital x and investing according to θ , then $X_0^{(x, \theta)} = x$ and

$$\begin{aligned} X_T^{(x, \theta)} &= \left(x - \sum_{i=1}^d \theta^i S_0^i \right) \frac{S_T^0}{S_0^0} + \sum_{i=1}^d \theta^i S_T^i \\ &= x \frac{S_T^0}{S_0^0} + \sum_{i=1}^d \theta^i \left(S_T^i - \frac{S_T^0}{S_0^0} S_0^i \right) \end{aligned} \quad (1)$$

or, in deflated terms, $\beta_T X_T^{(x, \theta)} = x + \sum_{i=1}^d \theta^i (\beta_T S_T^i - S_0^i)$. The agent's objective is to choose a strategy in such a way as to *maximize expected utility*, that is, find θ_* such that

$$\mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x, \theta_*)} \right) \right] = \sup_{\theta \in \mathbb{R}^d} \mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x, \theta)} \right) \right] \quad (2)$$

The above problem will indeed have a solution if and only if no arbitrage exists in the market. By definition, an *arbitrage* is a wealth generated by some $\theta \in \mathbb{R}^d$ such that $\mathbb{P}[X_T^{(x, \theta)} \geq 0] = 1$ and $\mathbb{P}[X_T^{(x, \theta)} > 0] > 0$. It is easy to see that arbitrage exists in the market if and only if $\sup_{\theta \in \mathbb{R}^d} \mathbb{E}^\mathbb{P}[U(X_T^{(x, \theta)})]$ is *not* attained by some $\theta_* \in \mathbb{R}^d$. Assuming, then, the *no-arbitrage* (NA) condition, concavity of the function $\mathbb{R}^d \ni \theta \mapsto \mathbb{E}^\mathbb{P}[U(X_T^{(x, \theta)})]$ will imply that the first-order conditions

$$\frac{\partial}{\partial \theta^i} \Big|_{\theta=\theta_*} \mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x, \theta)} \right) \right] = 0, \quad \text{for all } i = 1, \dots, d \quad (3)$$

will provide the solution θ_* to the problem. Since the expectation is just a finite sum, the differential operator can pass inside, and then the first-order conditions for optimality are

$$\begin{aligned} 0 &= \mathbb{E}^\mathbb{P} \left[\frac{\partial}{\partial \theta^i} \Big|_{\theta=\theta_*} U \left(X_T^{(x, \theta)} \right) \right] \\ &= \mathbb{E}^\mathbb{P} \left[U' \left(X_T^{(x, \theta_*)} \right) \left(S_T^i - \frac{S_T^0}{S_0^0} S_0^i \right) \right], \\ i &= 1, \dots, d \end{aligned} \quad (4)$$

The above is a nonlinear system of d equations to be solved for d unknowns $(\theta_*^1, \dots, \theta_*^d)$. Under NA, the system 4 has a solution θ_* . Actually, under a trivial nondegeneracy condition in the market, the solution is unique; even if the optimal strategy θ_* is not unique, strict concavity of U implies that the optimal wealth $X_T^{(x, \theta_*)}$ generated is unique.

A little bit of algebra on equation (4) gives, for all $i = 1, \dots, d$,

$$\begin{aligned} S_0^i &= \mathbb{E}^\mathbb{P} [Y_T S_T^i], \quad \text{where} \\ Y_T &:= \frac{U' \left(X_T^{(x, \theta_*)} \right)}{\mathbb{E}^\mathbb{P} \left[(S_T^0/S_0^0) U' \left(X_T^{(x, \theta_*)} \right) \right]} \end{aligned} \quad (5)$$

Observe that since U is continuously differentiable and strictly increasing, U' is a strictly positive function, and therefore $\mathbb{P}[Y_T > 0] = 1$. Also, equation (5) also holds trivially for $i = 0$. Note that the random variable Y_T that was obtained above depends on the utility function U , the probability $\mathbb{P}$, as well as on the initial capital $x \in \mathbb{R}$.

Definition 1 *In the model described above, a process $Y = (Y_t)_{t=0, T}$ will be called a stochastic discount factor if $\mathbb{P}[Y_0 = 1, Y_T > 0] = 1$ and $S_0^i = \mathbb{E}^\mathbb{P} [Y_T S_T^i]$ for all $i = 0, \dots, d$.*

If Y is a stochastic discount factor, using equation (1), one can actually show that

$$\mathbb{E}^\mathbb{P} [Y_T X_T^{(x, \theta)}] = x, \quad \text{for all } x \in \mathbb{R} \text{ and } \theta \in \mathbb{R}^d \quad (6)$$

In other words, the process $Y X^{(x, \theta)}$ is a $\mathbb{P}$ -martingale for all $x \in \mathbb{R}$ and $\theta \in \mathbb{R}^d$.

Connection with Risk-neutral Valuation

Since $\mathbb{E}^\mathbb{P} [S_T^0 Y_T] = S_0^0 > 0$, we can define a probability mass $\mathbb{Q}$ by requiring that $\mathbb{Q}(\omega) = (S_T^0(\omega)/S_0^0) Y_T(\omega) \mathbb{P}(\omega)$, which defines a probability $\mathbb{Q}$ on subsets of Ω in the obvious way. Observe that, for any $A \subseteq \Omega$, $\mathbb{Q}[A] > 0$ if and only if $\mathbb{P}[A] > 0$; we say that the probabilities $\mathbb{P}$ and $\mathbb{Q}$ are *equivalent* and we denote this by $\mathbb{Q} \sim \mathbb{P}$. Now, rewrite equation (5) as

$$S_0^i = \mathbb{E}^\mathbb{Q} [\beta_T S_T^i], \quad \text{for all } i = 0, \dots, d \quad (7)$$

A probability $\mathbb{Q}$, equivalent to $\mathbb{P}$, with the property prescribed in equation (7) is called *risk-neutral* or an *equivalent martingale measure*. In this simple framework, stochastic discount factors and risk-neutral probabilities are in one-to-one correspondence. In fact, more can be said.

Theorem 1 [Fundamental Theorem of Asset Pricing] *In the discrete model as described previously, the following three conditions are equivalent:*

1. *There are no arbitrage opportunities.*
2. *A stochastic discount factor exists.*
3. *A risk-neutral probability measure exists.*

The fundamental theorem of asset pricing was first formulated by Ross [11] and it took 20 years to reach a very general version of it in general semimartingale models that are beyond the scope of our treatment here. The interested reader can check the monograph [3], where the history of the theorem and all its proofs are presented.

The Important Case of the Logarithm

The most well-studied case of utility on the real line is $U(x) = \log(x)$, both because of its computational simplicity and for the theoretical value that it has. Since the logarithmic function is only defined on the strictly positive real line, it does not completely fall in the aforementioned framework, but it is easy to see that the described theory is still valid.

Consider an economic agent with logarithmic utility that starts with initial capital $x = 1$. Call $X^* = X^{(1; \theta_*)}$ the optimal wealth corresponding to log-utility maximization. The fact that $U'(x) = 1/x$ allows to define a stochastic discount factor Y^* via $Y_0^* = 1$ and

$$Y_T^* = \frac{1}{X_T^* \mathbb{E}^{\mathbb{P}}[1/(\beta_T X_T^*)]} \quad (8)$$

From $\mathbb{E}^{\mathbb{P}}[Y_T^* X_T^*] = 1$, it follows that $\mathbb{E}^{\mathbb{P}}[1/(\beta_T X_T^*)] = 1$ and therefore $Y^* = 1/X^*$. This simple relationship between the log-optimal wealth and the stochastic discount factor that is induced by it is one of the keys to characterize the existence of stochastic discount factors in more complicated models and their relationship with absence of free lunches. It finds good use in the section Stochastic Discount Factors for Itô Processes for the case of models using Itô processes.

Arbitrage-free Prices

For a claim with random payoff H_T at time T , an *arbitrage-free* (AF) price H_0 is a price at time zero such that the extended market that consists of the original traded assets with asset prices S^i , $i = 0, \dots, d$, augmented by the new claim, remains AF. If the claim is *perfectly replicable*, that is, if there exists $x \in \mathbb{R}$ and $\theta \in \mathbb{R}^d$ such that $X_T^{(x; \theta)} = H_T$, it is easily seen that the *unique* AF price for the claim is x . However, it is frequently the case that a newly introduced claim is not perfectly replicable using the existing liquid assets. In that case, there exists more than one AF price for the claim; actually, the set of all the possible AF prices is $\{\mathbb{E}^{\mathbb{P}}[Y_T H_T] \mid Y \text{ is a stochastic discount factor}\}$. To see this, first pick a stochastic discount factor Y_T and set $H_0 = \mathbb{E}[Y_T H_T]$; then, Y remains a stochastic discount factor for the extended market, which therefore does not allow for any arbitrage opportunities. Conversely, if H_0 is an AF price for the new claim, we know from Theorem 1 that there exists a stochastic discount factor Y for the extended market, which satisfies $H_0 = \mathbb{E}[Y_T H_T]$ and is trivially a stochastic discount factor for the original market. The result we just mentioned justifies the appellation “Fundamental theorem of asset pricing” for Theorem 1.

Utility Indifference Pricing

Suppose that a new claim promising some random payoff at time T is issued. Depending on the claim’s present traded price, an economic agent might be inclined to take a long or short position—this will depend on whether the agent considers the market price low or high, respectively. There does exist a market price level of the claim that will make the agent indifferent to going long or short on an *infinitesimal*^b amount of asset. This price level is called *indifference price*. In the context of claim valuation, utility indifference prices have been introduced in [2];^c however, they had been widely used previously in the science of economics. Indifference prices depend on the particular agent’s views, preferences, as well as portfolio structure, and should not be confused with market prices, which are established using the forces of supply and demand.

Since the discussed preference structures are based on *expected utility*, it makes sense to try and understand quantitatively how *utility indifference prices* are

formed. Under the present setup, consider a claim with random payoff H_T at time T . The question we wish to answer is this: what is the indifference price H_0 of this claim today for an economic agent?

For the time being, let H_0 be any price set by the market for the claim. The agent will invest in the risky assets and will hold θ units of them, as well as the new claim, taking a position of ϵ units. Then, the agent's terminal payoff is

$$X_T^{(x;\theta,\epsilon)} := X_T^{(x;\theta)} + \epsilon \left(H_T - \frac{S_T^0}{S_0^0} H_0 \right) \quad (9)$$

The agent will again maximize expected utility, that is, will invest $(\theta_*, \epsilon_*) \in \mathbb{R}^d \times \mathbb{R}$ such that

$$\mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x;\theta_*,\epsilon_*)} \right) \right] = \sup_{(\theta,\epsilon) \in \mathbb{R}^d \times \mathbb{R}} \mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x;\theta,\epsilon)} \right) \right] \quad (10)$$

If H_0 is the agent's indifference price, it must follow that $\epsilon_* = 0$ in the above maximization problem; then, the agent's optimal decision regarding the claim would be not to buy or sell any units of the asset. In particular, the concave function $\mathbb{R} \ni \epsilon \mapsto \mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x;\theta_*,\epsilon)} \right) \right]$ should achieve its maximum at $\epsilon = 0$. First-order conditions give that H_0 is the agent's indifference price if

$$\begin{aligned} 0 &= \frac{\partial}{\partial \epsilon} \Big|_{\epsilon=0} \mathbb{E}^\mathbb{P} \left[U \left(X_T^{(x;\theta_*,\epsilon)} \right) \right] \\ &= \mathbb{E}^\mathbb{P} \left[U' \left(X_T^{(x;\theta_*,0)} \right) \left(H_T - \frac{S_T^0}{S_0^0} H_0 \right) \right] \end{aligned} \quad (11)$$

A remark is in order before writing down the indifference-pricing formula. The strategy θ_* that has been appearing above represents the optimal holding in the liquid traded assets when *all* assets *and* the claim are available—it is *not*, in general, the agent's optimal asset holdings if the claim were *not* around. Nevertheless, *if* the solution of problem (10) is such that the optimal holdings in the claim are $\epsilon_* = 0$, *then* θ_* are also the agent's optimal asset holdings if there had been no claim to begin with. In other words, if $\epsilon_* = 0$, $X_T^{(x;\theta_*,0)}$ is exactly the same quantity $X_T^{(x;\theta_*)}$ that appears in equation (4). Remembering the definition of the stochastic discount factor Y_T of

equation (5), we can write

$$H_0 = \mathbb{E}^\mathbb{P} [Y_T H_T] \quad (12)$$

It is important to observe that Y_T depends on a number of factors, namely, the probability $\mathbb{P}$, the utility U , and the initial capital x , but *not* on the particular claim to be valued. Thus, we need only one evaluation of the stochastic discount factor and we can use it to find indifference prices with respect to all kinds of different claims.

State Price Densities

For a fixed $\omega \in \Omega$, consider an *Arrow–Debreu* security that pays off a unit of account at time T if the state of nature is ω , and pays off nothing, otherwise. The indifference price of this security for the economic agent is $p(\omega) := Y(\omega)P(\omega)$. Since Y appears as the density of the “state price” p with respect to the probability $\mathbb{P}$, stochastic discount factors are also termed *state price densities* in the literature. For two states of nature ω and ω' of Ω such that $Y(\omega) < Y(\omega')$, an agent who uses the stochastic discount factor Y would consider ω' a more unfavorable state than ω and would be inclined to pay more for insurance against adverse market movements.

Comparison with Real-world Valuation

Only for the purpose of what is presented here, assume that $S_0^0 = 1$ and $S_T^0 = 1 + rT$ for some $r \in \mathbb{R}_+$. Let Y be a stochastic discount factor; then, we have $1 = S_0^0 = \mathbb{E}^\mathbb{P} [Y_T S_T^0] = (1 + rT) \mathbb{E}^\mathbb{P} [Y_T]$. Pick any claim with random payoff H_T at time T and use $H_0 = \mathbb{E}^\mathbb{P} [Y_T H_T]$ to write

$$H_0 = \frac{1}{1 + rT} \mathbb{E}^\mathbb{P} [H_T] + \text{cov}^\mathbb{P} (Y_T, H_T) \quad (13)$$

where $\text{cov}^\mathbb{P}(\cdot, \cdot)$ is used to denote *covariance* of two random variables with respect to $\mathbb{P}$. The first term $(1 + rT)^{-1} \mathbb{E}^\mathbb{P} [H_T]$ of the above formula describes “real-world” valuation for an agent who would be neutral under his views $\mathbb{P}$ in facing the risk coming from the random payoff H_T . This risk-neutral attitude is usually absent: agents require compensation for the risk they undertake, or might even feel inclined to pay more for a security that will insure them in cases of unfavorable outcomes. This is exactly mirrored by the

correction factor $\text{cov}^{\mathbb{P}}(Y_T, H_T)$ appearing in equation (13). If the covariance of Y_T and H_T is negative, the claim tends to pay more when Y_T is low. By the discussion in the section State Price Densities, this means that the payoff will be high in states that are not greatly feared by the agent, who will therefore be inclined to pay *less* than what the real-world valuation gives. On the contrary, if the covariance of Y_T and H_T is positive, H_T will pay off higher in dangerous states of nature for the agent (where Y_T is also high), and the agent's indifference price will be *higher* than the real-world valuation.

Stochastic Discount Factors for Itô Processes

The Model

Uncertainty is modeled *via* a probability space $(\Omega, \mathcal{F}, \mathbf{F}, \mathbb{P})$, where $\mathbf{F} = (\mathcal{F}_t)_{t \in [0, T]}$ is a filtration representing the flow of information. The market consists of a *locally* riskless savings account whose price process S^0 satisfies $S^0_0 > 0$ and

$$\frac{dS^0_t}{S^0_t} = r_t dt, \quad t \in [0, T] \quad (14)$$

for some $\mathbf{F}$ -adapted, positive *short-rate* process $r = (r_t)_{t \in \mathbb{R}}$. It is obvious that $S^0_t = S^0_0 \exp(\int_0^t r_u du)$ for $t \in [0, T]$. We define the *deflator* β *via*

$$\beta_t = \frac{S^0_t}{S^0_0} = \exp\left(-\int_0^t r_u du\right), \quad t \in [0, T] \quad (15)$$

The movement of d risky assets will be modeled *via* Itô processes:

$$\frac{dS^i_t}{S^i_t} = b^i_t dt + \langle \sigma^i_t, dW_t \rangle, \quad t \in \mathbb{R}_+, \quad i = 1, \dots, d \quad (16)$$

Here, $b = (b^1, \dots, b^d)$ is the $\mathbf{F}$ -adapted d -dimensional process of *appreciation rates*, $W = (W^1, \dots, W^m)$ is an m -dimensional $\mathbb{P}$ -Brownian motion representing the *sources of uncertainty* in the market, and $\langle \cdot, \cdot \rangle$ denotes the usual inner product notation: $\langle \sigma^i_t, dW_t \rangle = \sum_{j=1}^m \sigma^{ji}_t dW^j_t$ where $(\sigma^{ji})_{1 \leq j \leq m, 1 \leq i \leq d}$ is the $\mathbf{F}$ -adapted $(m \times d)$ -matrix-valued process whose entry σ^{ji}_t represents the impact

of the j th source of uncertainty on the i th asset at time $t \in [0, T]$. With “ $\top$ ” denoting transposition, $c := \sigma^\top \sigma$ is the $d \times d$ local *covariation matrix*. To avoid degeneracies in the market, it is required that c_t has full rank for all $t \in [0, T]$, $\mathbb{P}$ almost surely (a.s.). This implies, in particular, that $d \leq m$ —there are more sources of uncertainty in the market than are liquid assets to hedge away the uncertainty risk. Models of this sort are classical in the quantitative finance literature—see, for example, [8].

Definition 2 *A risk premium is any m -dimensional, $\mathbf{F}$ -adapted process λ satisfying $\sigma^\top \lambda = b - r\mathbf{1}$, where $\mathbf{1}$ is the d -dimensional vector with all unit entries.*

The terminology “risk premium” is better explained for the case $d = m = 1$; then $\lambda = (b - r)/\sigma$ is the premium over the risk-free rate that investors require per unit of risk associated with the (only) source of uncertainty. In the general case, λ^j can be interpreted as the premium required for the risk associated with the j th source of uncertainty, represented by the Brownian motion W^j . In *incomplete* markets, when $d < m$, Proposition 1 shows all the different choices for λ . Each choice will parameterize the different risk attitudes of different investors. In other words, risk premia characterize the possible stochastic discount factors, as is revealed in Theorem 3.

If $m = d$, the equation $\sigma^\top \lambda = b - r\mathbf{1}$ has only one solution: $\lambda^* = \sigma c^{-1}(b - r\mathbf{1})$. If $d < m$ there are many solutions, but they can be characterized using easy linear algebra.

Proposition 1 *The risk premia are exactly all processes of the form $\lambda = \lambda^* + \kappa$, where $\lambda^* := \sigma c^{-1}(b - r\mathbf{1})$ and κ is any adapted process with $\sigma^\top \kappa = 0$.*

If $\lambda = \lambda^* + \kappa$ in the notation of Proposition 1, then $\langle \lambda^*, \kappa \rangle = (b - r\mathbf{1})^\top c^{-1} \sigma^\top \kappa = 0$. Then, $|\lambda|^2 = |\lambda^*|^2 + |\kappa|^2$, where $|\lambda^*|^2 = \langle b - r\mathbf{1}, c^{-1}(b - r\mathbf{1}) \rangle$.

Stochastic Discount Factors

The usual method of obtaining stochastic discount factors in continuous time is through risk-neutral measures. The fundamental theorem of asset pricing in the present Itô-process setting states that absence of free lunches with vanishing risk^d is equivalent to the existence of a probability $\mathbb{Q} \sim \mathbb{P}$ such that βS^i is (only) a *local* $\mathbb{Q}$ -martingale for all $i = 0, \dots, d$. (For

the definition of local martingales, check, e.g., [7].) In that case, by defining Y via $Y_t = \beta_t(d\mathbb{Q}/d\mathbb{P})|_{\mathcal{F}_t}$, YS^i is a local $\mathbb{P}$ -martingale for all $i = 0, \dots, d$. The last property is taken here as the *definition* of a stochastic discount factor.

Definition 3 Consider the above Itô-process setup, a stochastic process Y is called a stochastic discount factor if

- $Y_0 = 1$ and $Y_T > 0$, $\mathbb{P}$ a.s.
- YS^i is a local $\mathbb{P}$ -martingale for all $i = 0, 1, \dots, d$.

In the case where YS^0 is an actual martingale, that is, $\mathbb{E}^{\mathbb{P}}[Y_T S_T^0] = S_0^0$, a risk-neutral measure $\mathbb{Q}$ is readily defined via the recipe $d\mathbb{Q} = (Y_T S_T^0 / S_0^0) d\mathbb{P}$. However, this is not always the case, as Example 1 below will show. Therefore, existence of a stochastic discount factor is a weaker notion than existence of a risk-neutral measure. For some practical applications though, these differences are unimportant. There is further discussion of this point later in the section Stochastic Discount Factors and Equivalent Martingale Measures.

Example 1 Let $S^0 \equiv 1$ and S^1 be a three-dimensional Bessel process with $S_0^1 = 1$. If $\mathbf{F}$ is the natural filtration of S^1 , it can be shown that the *only* stochastic discount factor is $Y = 1/S^1$, which is a *strict local martingale* in the terminology of [4].

Credit Constraints on Investment

In view of the theoretical possibility of continuous trading, to avoid so-called *doubling strategies* (and for the fundamental theorem of asset pricing to hold), *credit constraints* have to be introduced. The wealth of agents has to be bounded from below by some constant, representing the credit limit. Shifting the wealth appropriately, one can assume that the credit limit is set to zero; therefore, only positive wealth processes are allowed in the market.

Since only strictly positive processes are considered, it is more convenient to work with *proportions* of investment, rather than absolute quantities as was the case in the section Stochastic Discount Factors in Discrete Probability Spaces. Pick some $\mathbf{F}$ -adapted process $\pi = (\pi^1, \dots, \pi^d)$. For $i = 1, \dots, d$ and $t \in [0, T]$, the number π_t^i represents the *percentage* of

capital in hand invested in asset i at time t . In that case, $\pi^0 = 1 - \sum_{i=1}^d \pi^i$ will be invested in the savings account. Denote by X^π the wealth generated by starting from unit initial capital ($X_0^\pi = 1$) and invest according to π . Then,

$$\frac{dX_t^\pi}{X_t^\pi} = \sum_{i=0}^d \pi_t^i \frac{dS_t^i}{S_t^i} = (r_t + \langle \pi_t, b_t - r_t \mathbf{1} \rangle) dt + \langle \sigma_t \pi_t, dW_t \rangle \quad (17)$$

To ensure that the above wealth process is well defined, we must assume that

$$\begin{aligned} \int_0^T |\langle \pi_t, b_t - r_t \mathbf{1} \rangle| dt < +\infty \text{ and} \\ \int_0^T \langle \pi_t, c_t \pi_t \rangle dt < +\infty, \quad \mathbb{P} \text{ a.s.} \end{aligned} \quad (18)$$

The set of all d -dimensional, $\mathbf{F}$ -adapted processes π that satisfy equation (18) is denoted by Π . A simple use of the integration-by-parts formula gives the following result:

Proposition 2 If Y is a stochastic discount factor, then YX^π is a local martingale for all $\pi \in \Pi$.

Connection with “No Free Lunch” Notions

The next line of business is to obtain an *existential* result about stochastic discount factors in the present setting, also connecting their existence to an NA-type notion. Remember, from the section The Important Case of the Logarithm, the special stochastic discount factor that is the reciprocal of the log-optimal wealth process. We proceed somewhat heuristically to compute the analogous processes for the Itô-process model. The linear stochastic differential equation (17) has the following solution, expressed in logarithmic terms:

$$\begin{aligned} \log X^\pi = \int_0^\cdot \left(r_t + \langle \pi_t, b_t - r_t \mathbf{1} \rangle - \frac{1}{2} \langle \pi_t, c_t \pi_t \rangle \right) dt \\ + \int_0^\cdot \langle \sigma_t \pi_t, dW_t \rangle \end{aligned} \quad (19)$$

Assuming that the local martingale term $\int_0^\cdot \langle \sigma_t \pi_t, dW_t \rangle$ in equation (19) is an actual martingale, the aim is to maximize the expectation of the drift

term. Notice that we can actually maximize the drift pathwise if we choose the portfolio $\pi_* = c^{-1}(b - r\mathbf{1})$. We need to ensure that π_* is in Π . It is easy to see that the equations in (18) are both satisfied if and only if $\int_0^T |\lambda_t^*|^2 dt < \infty$ $\mathbb{P}$ a.s., where $\lambda^* := \sigma c^{-1}(b - r\mathbf{1})$ is the special risk premium of Proposition 1. Under this assumption, $\pi_* \in \Pi$. Call $X^* = X^{\pi_*}$ and define

$$\begin{aligned} Y^* &:= \frac{1}{X^*} \\ &= \beta \exp \left(- \int_0^\cdot \langle \lambda_t^*, dW_t \rangle - \frac{1}{2} \int_0^\cdot |\lambda_t^*|^2 dt \right) \end{aligned} \quad (20)$$

Using the integration-by-parts formula, it is rather straightforward to check that Y^* is a stochastic discount factor. In fact, the ability to define Y^* is the way to establish that a stochastic discount factor exists, as the next result shows.

Theorem 2 *For the Itô process-model considered above, the following are equivalent.*

1. *The set of stochastic discount factors is nonempty.*
2. *$\int_0^T |\lambda_t^*|^2 dt < \infty$ $\mathbb{P}$ -a.s.; in that case, Y^* defined in equation (20) is a stochastic discount factor.*
3. *For any $\epsilon > 0$, there exists $\ell = \ell(\epsilon) \in \mathbb{R}_+$ such that $\mathbb{P}[X_T^\pi > \ell] < \epsilon$ uniformly over all portfolios $\pi \in \Pi$.*

The interest reader is referred to [6], where the property of the market described in statement 3 of the above theorem is termed *No Unbounded Profit with Bounded Risk*.

The next *structural* result about the stochastic discount factors in the Itô-process setting reveals the importance of Y^* as a building block.

Theorem 3 *Assume that $\mathbf{F}$ is the filtration generated by the Brownian motion W . Then, any stochastic discount factor Y in the previous Itô-process model can be decomposed as $Y = Y^* N^k$, where Y^* was defined in equation (20) and*

$$\begin{aligned} N_t^k &= \exp \left(- \int_0^t \langle \kappa_u, dW_u \rangle - \int_0^t |\kappa_u|^2 du \right), \\ &\forall t \in [0, T] \end{aligned} \quad (21)$$

where κ is an m -dimensional $\mathbf{F}$ -adapted process with $\sigma^\top \kappa = 0$.

If the assumption that $\mathbf{F}$ is generated by W is removed, one still obtains a similar result with N^k being replaced by *any* positive $\mathbf{F}$ -martingale N with $N_0 = 1$ that is *strongly* orthogonal to W . The specific representation obtained in Theorem 3 comes from the *martingale representation theorem* of Brownian filtrations; see, for example, [7].

Stochastic Discount Factors and Equivalent Martingale Measures

Consider an agent who uses a stochastic discount factor Y for valuation purposes. There is a possibility that YS^i could be a *strict local* $\mathbb{P}$ -martingale for some $i = 0, \dots, d$, which would mean that $S_0^i > \mathbb{E}^\mathbb{P}[Y_T S_T^i]$. The last inequality is puzzling in the sense that the agent's indifference price for the i th asset, which is $\mathbb{E}^\mathbb{P}[Y_T S_T^i]$, is *strictly* lower than the market price S_0^i . In such a case, the agent would be expected to wish to short some units of the i th asset. This is indeed what is happening; however, because of credit constraints, this strategy is infeasible. The following is a convincing example that establishes this fact. Before presenting the example, an important issue should be clarified. One would rush to state that such “inconsistencies” are tied to the notion of a stochastic discount factor as it appears in Definition 3, and that is *strictly* weaker than existence of a probability $\mathbb{Q} \sim \mathbb{P}$ that makes all discounted processes βS^i *local* $\mathbb{Q}$ -martingales for $i = 0, \dots, d$. Even if such a probability *did* exist, βS^i could be a *strict local* $\mathbb{Q}$ -martingale for some $i = 1, \dots, d$; in that case, $S_0^i > \mathbb{E}^\mathbb{Q}[\beta_T S_T^i]$ and the same mispricing problem pertains.

Example 2 Let $S^0 \equiv 1$, S^1 be the *reciprocal* of a three-dimensional Bessel process starting at $S_0^1 = 1$ under $\mathbb{P}$ and $\mathbf{F}$ be the filtration generated by S^1 . Here, $\mathbb{P}$ is the *only* equivalent local martingale measure and $1 = S_0^1 > \mathbb{E}^\mathbb{P}[S_T^1]$ for all $T > 0$. This is a *complete* market—an agent can start with capital $\mathbb{E}^\mathbb{P}[S_T^1]$ and invest in a way so that at time T the wealth generated is exactly S_T . Naturally, the agent would like to long as much as possible from this replicating portfolio and go as short as possible from the actual asset. However, in doing so, the possible downside risk is infinite throughout the life of the investment and the enforced credit constraints will disallow for such strategies.

In the context of Example 2, the law of one price fails, since the asset that provides payoff S_T^1 at time T has a market price S_0^1 and a replication price $\mathbb{E}^\mathbb{P}[S_T^1] < S_0^1$. Therefore, if the law of one price is to be valid in the market, one has to insist on existence of an equivalent (*true*) martingale measure $\mathbb{Q}$, where each discounted process βS^i is a *true* (and not only local) $\mathbb{Q}$ -martingale for all $i = 0, \dots, d$. For pricing purposes then, it makes sense to ask that the stochastic discount factor Y^κ that is chosen according to Theorem 3 is such that $Y^\kappa S^i$ is a true $\mathbb{P}$ -martingale for all $i = 0, \dots, d$. Such stochastic discount factors give rise to probabilities $\mathbb{Q}^\kappa$ that make all deflated asset-price-process $\mathbb{Q}^\kappa$ -martingales and can be used as pricing measures.

Let us now specialize to the important “diffusion” case where $r_t = r \in \mathbb{R}$ for all $t \in [0, T]$ and $\sigma_t = \eta(t, S_t)$ for all $t \in [0, T]$, where η is a nice function with values in the space of $(m \times d)$ -matrices. As long as a claim written only on the traded assets is concerned, the choice of $\mathbb{Q}^\kappa$ for pricing is irrelevant, since the asset prices under $\mathbb{Q}^\kappa$ have dynamics

$$\frac{dS_t^i}{S_t^i} = r_t dt + \langle \sigma_t^i, dW_t^\kappa \rangle, \quad \forall t \in [0, T], \quad i = 1, \dots, d \quad (22)$$

where W^κ is a $\mathbb{Q}^\kappa$ -Brownian motion. However, if one is interested in pricing a claim written on a nontraded asset whose price process Z has $\mathbb{P}$ -dynamics

$$dZ_t = a_t dt + \langle f_t, dW_t \rangle, \quad t \in [0, T] \quad (23)$$

for $\mathbf{F}$ -adapted a and $f = (f^1, \dots, f^m)$, then the $\mathbb{Q}^\kappa$ -dynamics of Z are

$$dZ_t = (a_t - \langle f_t, \lambda_t^* \rangle - \langle f_t, \kappa_t \rangle) dt + \langle f_t, dW_t^\kappa \rangle, \quad \forall t \in [0, T] \quad (24)$$

The dynamics of Z will be independent of the choice of κ only if the volatility structure of the process Z , given by f , is in the range of $\sigma^\top$. This will mean that $\langle f, \kappa \rangle = 0$ for all κ such that $\sigma^\top \kappa = 0$ and that Z is perfectly replicable using the traded assets. As long as there is any randomness in the movement in Z that cannot be captured by investing in the traded assets, that is, if there exists some κ with $\sigma^\top \kappa = 0$ and $\langle f, \kappa \rangle$ not being identically zero, perfect replicability fails and pricing becomes a more complicated

issue, depending on the preferences of the particular agent as given by the choice of κ to form the stochastic discount factor.

End Notes

^aOne can impose natural conditions on preference relations defined on the set of all possible outcomes that will lead to numerical representation of the preference relationship *via* expected utility maximization. This was axiomatized in [10]—see also Chapter 2 of [5] for a nice exposition.

^bWe stress “infinitesimal” because when the portfolio holdings of the agent change, the indifference prices also change; thus, for large sales or buys that will considerably change the portfolio structure, there might appear an incentive, that was not there before, to sell or buy the asset.

^cFor this reason, utility indifference prices are sometimes referred to as *Davis prices*.

^dFree lunches with vanishing risk is the suitable generalization of the notion of arbitrages to get a version of the fundamental theorem of asset pricing in continuous time. The reader is referred to [3].

^eThe inequality follows because positive local martingales are supermartingales—see, for example, [7].

Utility Function

Behavior and Preferences

Modern utility theory studies preference orderings over choice sets and their numerical representations. Consider a decision maker (DM) who has to choose among a set X of alternatives. The set X is called the *DM's choice set*. In the deterministic case, which is our focus here, alternatives are certain, without any uncertainty. For example, in consumer theory, the DM is a consumer and X is the consumption set that he/she faces, that is, a subset of $\mathbb{R}^n$ whose elements $x = (x_1, \dots, x_n)$ represent the consumption bundles available to consumers. In intertemporal choice problems, X is a subset of $\mathbb{R}^\infty$, the space of sequences $\{x_t\}_{t=1}^\infty$, where x_t is the DM's outcome at time t . Alternatives become more complicated objects under uncertainty, such as random variables in one-period problems and stochastic processes in intertemporal problems. This more general case is not considered here.

DMs have some preferences over the elements of X ; they may like some alternatives more than others or may be indifferent among some of them. For example, in consumer theory consumers will rank consumption bundles in their consumption sets according to their tastes.

This motivates the introduction of preference orderings $\succsim$ defined on the choice set X . The ordering $\succsim$ has the following interpretation: for any two vectors x and y in X , we write $x \succsim y$ if the DM either strictly prefers x to y or is indifferent between the two.

The ordering $\succsim$ is the basic primitive of the theory. The following two relations are derived from $\succsim$:

1. for any two vectors x and y in X , we write $x \succ y$ if the DM strictly prefers x to y . Formally, $x \succ y$ if $x \succsim y$, but not $y \succsim x$;
2. for any two vectors x and y in X , we write $x \sim y$ if the DM is indifferent between x and y . Formally, $x \sim y$ if both $x \succsim y$ and $y \succsim x$.

On the preference ordering $\succsim$, which is the theory's "raw material," some properties are considered.

Axiom 1 (Transitivity). *For any three elements x, y , and z in X , if $x \succsim y$ and $y \succsim z$, then $x \succsim z$.*

Transitivity is a rationality assumption. Its violation generates cycles, for example, $x \succsim y \succsim z \succ x$. The most troublesome consequence of such cycles is that there might not exist a best element in the choice set X . For example, suppose that $X = \{x, y, z\}$ and that $x \succ y$ and $y \succ z$. If transitivity is violated, we get the cycle $x \succ y \succ z \succ x$ and there is no best element in X .

Axiom 2 (Completeness). *For any two elements x and y in X , $x \succsim y$, $y \succsim x$, or both.*

This is a simple, but not innocuous, property. A DM's preference $\succsim$ satisfies this property if, when faced with any two alternatives in X , he/she can always say which one he/she prefers. As alternatives may be very different, this might be a strong requirement (see [1, 6], for weakenings of this assumption).

Note that Axiom 2 implies reflexivity, that is, $x \succsim x$ for all $x \in X$. When $\succsim$ is reflexive and transitive (e.g., when it satisfies Axioms 1 and 2), following the consumer theory terminology, we call indifference curves the equivalence classes $[x] = \{y \in X : y \sim x\}$ for any $x \in X$. We denote the collection $\{[x] : x \in X\}$ of all indifference curves by $X/\sim$, which is a partition of X . That is, each $x \in X$ belongs to one, and only one, indifference curve.

Axioms 1 and 2 do not depend on any particular structure of the set X . In most applications, however, X is a subset of an ordered vector space $(V, \geq)$, that is, of a space V that has both a vector and an order structure. The space $\mathbb{R}^n$ endowed with the natural order $\geq$ is an important example of an ordered vector space. Given any $x, y \in \mathbb{R}^n$, when the vectors x and y are regarded as consumption bundles, $x \geq y$ means that the bundle x has at least as much of each good than the bundle y , while the convex combination $\alpha x + (1 - \alpha)y$ is interpreted as a mix of the two vectors (implicitly we are assuming that goods are suitably divisible).

The following axioms are based on the order and vector structures of X . For simplicity, we assume $X \subseteq \mathbb{R}^n$, though most of what follows holds in more general ordered vector spaces with units. Here, $x \succ y$ means $x \geq y$ and $x \neq y$ (i.e., $x_i > y_i$ for at least some $i = 1, \dots, n$).

Axiom 3 (Monotonicity). *For any two elements x and y in $X \subseteq \mathbb{R}^n$, if $x \succ y$, then $x \succ y$.*

This axiom connects the order $\geq$ on X and the DM's preference relation $\succsim$. In the context of consumer theory, it says that “the more, the better.” In particular, given two vectors x and y with $x \geq y$, it is enough that x has strictly more of at least some good i to be strictly preferred to y . This means that all goods are “essential” that is, the DM pays attention to each of them. Moreover, observe that, by Axiom 3 and reflexivity, $x \geq y$ implies $x \succsim y$. This is because $x \geq y$ if either $x = y$ or $x > y$.

The following two axioms rely on the vector structure of X .

Axiom 4 (Archimedean). *Suppose that x , y , and z are any three elements of a convex $X \subseteq \mathbb{R}^n$ such that $x > y > z$. Then there exist $\alpha, \beta \in (0, 1)$ such that $\alpha x + (1 - \alpha)z > y > \beta x + (1 - \beta)z$.*

According to this axiom, there are no infinitely preferred or infinitely despised alternatives. That is, given any pairs $x > y$ and $y > z$, alternative x cannot be infinitely better than y , and alternative z cannot be infinitely worse than y . Indeed, we can always mix x and z to get better alternatives, that is, $\alpha x + (1 - \alpha)z$, or worse alternatives, that is, $\beta x + (1 - \beta)z$, than y .

It may be useful to remember the analogous property that holds for real numbers: if x , y , and z are real numbers with $x > y > z$, then there exist $\alpha, \beta \in (0, 1)$ such that $\alpha x + (1 - \alpha)z > y > \beta x + (1 - \beta)z$. This property does not hold any more if we consider ∞ and $-\infty$, that is, the extended real line $\mathbb{R} = [-\infty, \infty]$. Specifically, let $x = \infty$ or $z = -\infty$. In this case, x is infinitely larger than y , z is infinitely smaller than y , and there are no $\alpha, \beta \in (0, 1)$ that satisfy the previous inequality. In fact, $\alpha\infty = \infty$ and $\beta(-\infty) = -\infty$ for all $\alpha, \beta \in (0, 1)$.

Axiom 5 (Convexity). *Given any two elements x and y of a convex set $X \subseteq \mathbb{R}^n$, if $x \sim y$ then $\alpha x + (1 - \alpha)y \succsim x$ for all $\alpha \in [0, 1]$.*

This axiom captures a preference for mixing: given any two indifferent alternatives, the DM always prefers any of their combination to each of the original alternatives. This preference for mixing is often assumed in applications and is a convexity property of indifference curves,^a the modern counterpart of the classic assumption of diminishing marginal utility.

Summing up, we have introduced a few properties that are often assumed on the preference $\succsim$. All these axioms are behavioral, that is, they are expressed

in terms of choice behavior. In particular, their behavioral meaning is transparent and, with the exception of the Archimedean axiom, they are all behaviorally falsifiable by suitable choice patterns. For example, one can show that a DM does not satisfy the transitivity axiom by finding alternatives $x, y, z \in X$ over which his/her choices exhibit the cycle $x \succsim y \succsim z > x$. This choice pattern would be enough to reject the hypothesis that his/her preference over X is transitive.

The use of preference axioms that have a transparent behavioral interpretation and that are falsifiable through choice behavior is the main methodological tenet of modern utility theory, often called the *revealed preference methodology*. In fact, choice behavior data are regarded as the only observable data that economic theories can rely upon.

Another important methodological feature of modern utility theory is that it adopts a weak notion of rationality, which requires only the consistency of choices without any demand on their motives. For example, transitivity is viewed as a rationality requirement in this sense because its violations would entail inconsistent patterns of choices that no DM would consciously follow, regardless of his/her motivations (see [15], for a recent discussion of this methodological issue).

Paretian Utility Functions

Although the preference ordering $\succsim$ is the fundamental notion, for analytical convenience it is often of interest to find a numerical representation of $\succsim$. Such numerical representations are called *utility functions*; formally, a real-valued function $u : X \rightarrow \mathbb{R}$ is a (*Paretian*) *utility function* if, for any pair $x, y \in X$,

$$x \succsim y \quad \text{if and only if} \quad u(x) \geq u(y) \quad (1)$$

In particular, for the derived relations $>$ and $\sim$ it holds, respectively, $x > y$ if and only if $u(x) > u(y)$ and $x \sim y$ if and only if $u(x) = u(y)$. Indifference curves can thus be written in terms of utility functions as $[x] = \{y \in X : u(y) = u(x)\}$.

Utility functions are analytically very convenient, but do not have any intrinsic psychological meaning: what matters is that they numerically rank vectors in the same way as the preference ordering $\succsim$. This implies, *inter alia*, that every monotone

transformation of a utility function is still a utility function, that is, utility functions are invariant under monotone transformations. To see why this is the case, let $u(X) = \{u(x) : x \in X\} \subseteq \mathbb{R}$ be the range of u and $f : u(X) \rightarrow \mathbb{R}$ a (strictly) monotone function, that is, $t > s$ implies $f(t) > f(s)$ for any scalars $t, s \in u(X)$. Clearly, $x \succsim y$ if and only if $(f \circ u)(x) \geq (f \circ u)(y)$ for any pair $x, y \in X$, and this shows that the transformation $f \circ u$ is still a utility function.

Example 1 A classic utility function $u : \mathbb{R}_{++}^2 \rightarrow \mathbb{R}$ is the Cobb–Douglas utility function:

$$u(x, y) = x^a y^{1-a} \quad \text{with } 0 \leq a \leq 1 \quad (2)$$

Suppose a preference $\succsim$ is represented by a Cobb–Douglas utility function. Then, $\succsim$ is also represented by the following monotone transformations of u :

1. $\lg(u(x, y)) = \lg(x^a y^{1-a}) = a \lg x + (1-a) \lg y$;
2. $\sqrt{u(x, y)} = \sqrt{x^a y^{1-a}} = x^{\frac{a}{2}} y^{\frac{1-a}{2}}$; and
3. $u(x, y)^3 = x^{3a} y^{3(1-a)}$.

In view of this invariance under monotone transformations, the utility theory presented here is often called *ordinal utility theory*. Observe that in this ordinal theory, utility differences such as $u(x) - u(y)$ are of no interest. This is because inequalities such as $u(x) - u(y) \geq u(z) - u(w)$ have no meaning in this setup: given any such inequality, it is easy to come up with monotone transformations $f : \mathbb{R} \rightarrow \mathbb{R}$ such that $(f \circ u)(x) - (f \circ u)(y) < (f \circ u)(z) - (f \circ u)(w)$. An important consequence of this observation is that incremental ratios of utility functions defined on subsets of $\mathbb{R}^n$ have no interest, except for their sign. For example, the classic notion of decreasing marginal utility, which is based on properties of the partial derivatives $\partial u(x)/\partial x_k$, is thus meaningless in ordinal utility theory.

In applications, utility functions $u : X \rightarrow \mathbb{R}$ are often used in optimization problems

$$\max_{x \in C} u(x) \quad (3)$$

where C is a suitable subset of the choice set X , determined by possible constraints that limit the DM's choices. For example, in consumer theory, C

is given by the budget set

$$C = \left\{ x \in X : \sum_{i=1}^n p_i x_i \leq w \right\} \quad (4)$$

where w is the consumer's wealth and each p_i is the price per unit of good i .

It is immediately seen that the solutions of the optimization problem (3) are the same, regardless of what monotone transformation of u is selected to make calculations. On the other hand, all these monotone transformations represent the same preference $\succsim$ and the solutions reflect only the DM's basic preference $\succsim$, not the particular utility function used to represent $\succsim$. This further shows that $\succsim$ is the fundamental notion. The choice of which u to use, among all equivalent monotone transformations, is only a matter of analytical convenience (e.g., in the Cobb–Douglas case, it is often convenient to use the logarithmic version $a \lg x + (1-a) \lg y$).

The optimization problems (3), which play a key role in economics, also illustrate the analytical importance of utility functions. In fact, a numerical representation of preferences allows to use the powerful methods of optimization theory to find and characterize the solutions of problem (3), which would be otherwise impossible, if we were to only rely on the preference $\succsim$. In other words, though the study of the preference $\succsim$ is what gives ordinal utility theory its scientific status by making it a behaviorally founded and falsifiable theory, it is its numerical representation provided by utility functions that gives the theory its operational content.

Given the importance of utility functions, the main problem of ordinal utility theory is to establish conditions under which the preference ordering $\succsim$ admits a utility representation. This is not a simple problem. We first state an existence result for the special case when the collection $X/\sim$ of indifference curves is at most countable.

Theorem 1 A preference ordering $\succsim$ defined on a choice set X with $X/\sim$ at most countable satisfies Axioms 1 and 2 if and only if there exists a function $u : X \rightarrow \mathbb{R}$ such that equation (1) holds.

Proof 1 [12] page 14.

Matters are more complicated when the collection $X/\sim$ is uncountable. It is easy to come up with examples of preferences that satisfy Axioms 1 and 2 and

do not admit a utility representation (see Example 2). We refer to [2, 12, 18] for general representation theorems. Here we establish an existence result for the important special case of preferences defined on $\mathbb{R}^n$, based on [3]. It is closely related to Theorems 3.3 and 3.6 of Fishburn (1970). For brevity, we omit its proof.

Write $x \leq \infty$ (respectively, $x \geq -\infty$) when either $x \in \mathbb{R}^n$ or $x_i = \infty$ (respectively, $x_i = -\infty$) for each i . That is, $x \leq \infty$ or $x \geq -\infty$ means that either each x_i is finite or each x_i is infinite. A subset of $\mathbb{R}^n$ is a closed order interval if, given $-\infty \leq y < z \leq \infty$, it has the form $[y, z] = \{x \in \mathbb{R}^n : y \leq x \leq z\}$ and is an open order interval if it has the form $(y, z) = \{x \in \mathbb{R}^n : y_i < x_i < z_i \text{ for each } i\}$. The half-open order intervals $[y, z)$ and $(y, z]$ are similarly defined. For example, $[z, \infty) = \{x \in \mathbb{R}^n : x \geq z\}$, and so $[0, \infty) = \mathbb{R}_+^n$.

A function $u : X \rightarrow \mathbb{R}$ is *monotone* if $x > y$ implies $u(x) > u(y)$ and is *quasiconcave* if its upper sets $\{x : u(x) \geq t\}$ are convex for all $t \in \mathbb{R}$ [16]. Since $\{y : u(y) \geq u(x)\} = \{y : y \succeq x\}$, the quasi-concavity of u implies the convexity of the upper contour sets of indifference curves (cf. End Note a).

Theorem 2 *For a preference ordering $\succeq$ defined on a order interval $X \subseteq \mathbb{R}^n$, the following conditions are equivalent:*

1. $\succeq$ satisfies Axioms 1–4 and
2. *there exists a monotonic and continuous function $u : X \rightarrow \mathbb{R}$ such that equation (1) holds.*

Moreover, Axiom 5 holds if and only if u is quasiconcave.

Theorem 2 is an important result. Almost every work in economics contains a utility function, often defined on order intervals of $\mathbb{R}^n$ and assumed to be monotone and quasi-concave. Theorem 2 shows the behavioral conditions that underlie this key modeling assumption.

By Theorem 2, the convexity axiom 5 is equivalent to the quasi-concavity of the utility function u . This is a substantially weaker property than the concavity of u , which would require $u(\alpha x + (1 - \alpha)y) \geq \alpha u(x) + (1 - \alpha)u(y)$ for all $x, y \in X$ and all $\alpha \in [0, 1]$. For example, any increasing function $u : \mathbb{R} \rightarrow \mathbb{R}$ is automatically quasi-concave.

Since concave utility functions are often used in applications because of their remarkable properties in

optimization problems, a natural question is whether, among all monotone transformations $f \circ u$ of a quasi-concave utility function u , there exists a concave one and this would ensure the existence of a concave representation of a preference $\succeq$ that satisfies Axiom 5. This important question was first studied by de Finetti [11], who showed that there exist quasi-concave functions that do not have any concave monotone transformation. Hence, convex indifference curves are not necessarily determined by a concave utility function (the converse is obviously true) and quasiconcavity in Theorem 2 cannot be improved to concavity. *Inter alia*, the seminal paper of de Finetti started the study of quasi-concave functions, later substantially developed by Fenchel [8], which is arguably the most important generalization of concavity.

Finally, observe that the utility function in Theorem 2 is continuous even though none of the axioms involves any topological notion. This is a remarkable consequence of the order and vector structures that the axioms use.

We close with an example of a preference that does not admit a utility representation.

Example 2 Lexicographic preferences are a classic example of preference orderings that do not admit a utility representation. Set $X = \mathbb{R}^2$ and say that $x \succeq y$ if either $x_1 > y_1$ or $x_1 = y_1$ and $x_2 \geq y_2$. That is, the DM first looks at the first coordinate: if $x_1 > y_1$, then $x \succeq y$. However, if $x_1 = y_1$, then the DM turns his/her attention to the second coordinate: if $x_2 \geq y_2$, then $x \succeq y$. This is how dictionaries order words and this motivates the name of this particular ordering. Although they satisfy Axioms 1–3, it can be proved ([18], pages 24–25) that lexicographic preferences do not admit a utility representation (it is easy to check that they do not satisfy the Archimedean axiom).

Brief Historical Remarks

The early development of utility theory is surveyed in the two 1950 articles of George Stigler [24]. Here it is worth noting that originally utility functions were regarded as a primitive notion whose role was to quantify a Benthamian pain/pleasure calculus. In other words, utility functions were viewed as a measure or a quantification of an underlying physiological phenomenon. This view of utility theory is sometimes called *cardinalism* and utility

functions derived within this approach are called *cardinal utility functions*. A key feature of cardinalism is that utility differences and their ratios are meaningful notions that quantify differences in pain/pleasure that DMs experience among different quantities of the outcomes. In particular, marginal utilities measure the marginal pain/pleasure that results from choices and these played a central role in the early cardinal consumer theory.

However, the difficulty of any reliable scientific measurement of cardinal utility raised serious doubts on the scientific status of cardinalism. At the end of the nineteenth century Pareto revolutionized utility theory by showing that an ordinal approach, based on indifference curves as a primitive notion—unlike Edgeworth [7], who introduced them as level curves of an original cardinal utility function—was enough for consumer theory purposes [20]. In particular, Pareto showed that the classic consumer problem could be solved and characterized by replacing marginal utilities with marginal rates of substitutions along indifference curves. For example, the classic key assumption of diminishing marginal utilities is replaced by the convexity property (Axiom 5) of indifference curves (the latter is actually a stronger property, unless utility functions are separable).

Unlike cardinal utility functions, indifference curves and their properties can be empirically determined and tested. Pareto's insight thus represented a key methodological advance and his ordinal approach, later substantially extended by Hicks and Allen [17, 23], is today the mainstream version of consumer theory. More generally, Pareto's ordinal revolution paved the way to the modern use of preferences as the primitive notion of decision theory. In fact, the use of preferences is the natural conceptual development of Pareto's original insight of considering indifference curves as a primitive notion. The first appearance of preferences as primitive notions seems to be in [9, 13]. They earned their current central theoretical place in decision theory with the classic works [4, 9, 12].

The utility theory under certainty outlined here reached its maturity in the 1960s (see, e.g., [5]). Subsequent work on decision theory has been mainly concerned with choice under uncertainty, extending the scope of the seminal contributions [9, 10, 19, 21, 22]. We refer the reader to [14] for a thorough and updated introduction to these more recent advances.

End Notes

^aObserve that this convexity property of indifference curves is weaker than the convexity of their upper contour sets $\{y \in X : y \succsim x\}$.

Recursive Preferences

The standard additive utility model defines time- t utility for a discrete-time consumption process $\{c_t; t = 1, \dots, T\}$ as

$$U_t = E_t \sum_{s=t}^T e^{-\beta(s-t)} u(c_s) = E_t \{u(c_t) + e^{-\beta} U_{t+1}\} \quad (1)$$

where E_t denotes the conditional expectation. The virtue of the model is its simplicity: only discounted probabilities and the function u determine preferences. However, the additive treatment of states and times precludes the model from distinguishing between aversion to variability in consumption across states and across time. In fact, the agent's preferences are entirely determined by preferences over deterministic consumption streams (see [23]). Furthermore, because agents care only about the distribution of future consumption, they do not care about the temporal resolution of uncertainty.

A more flexible preference model is obtained with Krep and Porteus [14] recursive specification (see also [11]):

$$U_t = F(c_t, E_t u(U_{t+1})), \quad U_T = v(c_T) \quad (2)$$

where the aggregator function F models intertemporal substitution and u the aversion to risk in next period's utility. The popular Epstein and Zin [12] model is the special case characterized by scale-invariant preferences (U_t homogeneous in (c_t, U_{t+1})) and $v(c) = c$ and constant elasticity of substitution. The stochastic differential utility (SDU) formulation

$$U_t = E_t \left(\int_{s=t}^T b(c_s, U_s) ds + \frac{1}{2} a(U_s) d[U, U]_s \right) \quad (3)$$

where $[\cdot, \cdot]$ denotes quadratic variation, which was obtained by Duffie and Epstein [8] as the continuous-time limit of recursive utility. Time-additive utility is the special case $b(c, U) = u(c) - \beta U$ and $a = 0$. Skiadas [22] shows that SDU includes the robust control formulations of Anderson *et al.* [1], Hansen *et al.* [13], and Maenhout [17]. It is straightforward to show that SDU also includes the continuous-time limit of Chew [3] and Dekel [7] preferences.

In this paper, we examine the generalized SDU model, given in differential form by equation (5).

This preference model was introduced by Lazrak and Quenez [15] to unify the recursive formulation of Duffie and Epstein [8] and multiple-prior formulation of Chen and Epstein [2]. Schroder and Skiadas [19] and Skiadas [23] (see also [20] for the case with jumps) show that the more flexible form of the aggregator allows preferences to depend on the source of risk (e.g., domestic *versus* foreign), as well as first-order risk aversion (which imposes a higher penalty for small levels of risk) in addition to the standard second-order risk aversion dependence in equation (3).^a

Relative to the time-additive model, the loss of tractability under generalized SDU is surprisingly small and mainly confined to the complete-markets setting. In the case of power utility, for example, once incompleteness or market constraints are imposed, the additive problem is no simpler to solve than a more general class of scale-invariant (homothetic) recursive utility. The tractability of the most popular additive utility models is obtained not from additivity but from the scale or translation invariance property. The second and third sections examine the recursive classes with these invariance properties and show that their solution essentially reduces to solving a single constrained backward stochastic differential equation.

After defining the preferences and markets in the second and third sections, the general solution to the optimal portfolio and consumption problem is presented in the fourth section. The solution is obtained by first characterizing the utility supergradient density (a generalization of marginal utility) and the state-price density. The state-price result is useful in other asset-pricing applications because it characterizes the set of pricing operators consistent with no arbitrage in a general market setting.^b The optimal consumption process is obtained by equating a supergradient density and state-price density (a generalized notion of equating marginal utility and prices). All results in this article are based on [18–20]; these references also develop more specialized and tractable formulations, based on quadratic modeling of risk aversion, and the last introduces jump risk (modeled by marked point processes).

All uncertainty is generated by d -dimensional standard Brownian motion B over the finite time horizon $[0, T]$, supported by a probability space $(\Omega, \mathcal{F}, P)$. All processes dealt with in this article are assumed to be progressively measurable with respect to the augmented filtration $\{\mathcal{F}_t : t \in [0, T]\}$ generated

by B . We define a *cash flow* as a process x such that $E \left[\int_0^T x_t^2 dt + x_T^2 \right] < \infty$. We interpret x_t as a time- t payment rate and x_T as a lump-sum terminal payment. The set of all cash flows is denoted $\mathcal{H}$, which we regard as a Hilbert space under the inner product

$$(x|y) = E \left[\int_0^T x_t y_t dt + x_T y_T \right], \quad x, y \in \mathcal{H} \quad (4)$$

The set of *consumption plans* is the convex cone $\mathcal{C} \subseteq \mathcal{H}$. Finally, we let $\mathcal{S}_p$, $p = 1, 2$, denote the set of cash flows, satisfying $E \left[\left(\text{ess sup}_{t \in [0, T]} |x_t|^p \right) \right] < \infty$. The qualification “almost surely” is omitted throughout. The coefficients of all the stochastic differential equations introduced will be assumed sufficiently integrable so that the equations are well defined.

Recursive Preferences

We define preferences in terms of a *utility aggregator*, $F : \Omega \times [0, T] \times \mathbb{R}^{2+d} \rightarrow \mathbb{R}$. For every consumption plan $c \in \mathcal{C}$, we assume that there is a unique solution (U, Σ) to the backward stochastic differential equation (BSDE):

$$\begin{aligned} dU_t &= -F(t, c_t, U_t, \Sigma_t) dt + \Sigma_t' dB_t, \\ U_T &= F(T, c_T) \end{aligned} \quad (5)$$

(terminal utility depends only on (ω, T, c_T)), and we define $U(c) = U$. Throughout we assume that F is differentiable, $F(\omega, t, \cdot)$ is concave, and that the range of $F_c(\omega, t, \cdot, U, \Sigma)$ is $(0, \infty)$. SDU is the special case $F(\omega, t, c, U, \Sigma) = b(\omega, t, c, U) + \frac{1}{2}a(\omega, t, U)\Sigma'\Sigma$, and standard additive utility corresponds to the linear aggregator $F(\omega, t, c, U, \Sigma) = u(t, c) - \beta(t)U$. A multiple-priors formulation of [2] is given by

$$dU_t = - \left(b(t, c_t, U_t) - \max_{\theta \in \Theta_t} \theta' \Sigma_t \right) dt + \Sigma_t' dB_t \quad (6)$$

for some function Θ from $\Omega \times [0, T]$ to the set of convex compact subsets of $\mathbb{R}^d$.

Markets and the Wealth Equation

The agent is endowed with initial financial wealth w_0 and an endowment process $e \in \mathcal{H}$. The dollar value of

the agent's position in m risky assets is represented by the process $\phi = (\phi^1, \dots, \phi^m)'$. The agent's financial wealth process (not including the present value of the future endowment), W , is defined in terms of the *wealth aggregator* $f : \Omega \times [0, T] \times \mathbb{R}^{m+1} \rightarrow \mathbb{R}$, which represents the instantaneous expected growth of the agent's portfolio. Cuoco and Cvitanic [4] propose a nonlinear wealth aggregator to model the price impact of a large investor or differential borrowing and lending rates. Trading and wealth constraints are modeled by requiring the vector (W_t, ϕ_t) to lie in a convex set $K \subseteq \mathbb{R}^{1+m}$ at all times. The returns diffusion matrix is an $\mathbb{R}^{d \times m}$ -valued process σ^R . The agent's plan (c, W, ϕ) is *feasible* if it satisfies the *budget equation*

$$\begin{aligned} dW_t &= (f(t, W_t, \phi_t) + e_t - c_t)dt + \phi_t' \sigma_t^{R'} dB_t, \\ W_0 &= w_0, \quad c_T = W_T + e_T, \quad (W_t, \phi_t) \in K \end{aligned} \quad (7)$$

and the integrability conditions $\int_0^t (|f(s, W_s, \phi_s)| + \phi_s' \sigma_s^{R'} \sigma_s^R \phi_s) ds < \infty$ and $(-W_t)^+ \in \mathcal{S}_2$ (the latter to rule out doubling-type strategies). A consumption plan c is feasible if it is part of a feasible plan (c, W, ϕ) .

Example 1 Linear Budget Equation. Suppose that a money-market security pays interest at a rate r_t , and the risky assets' instantaneous excess returns relative to r are $dR_t = \mu_t^R dt + \sigma_t^{R'} dB_t$. Then we get the standard case:

$$\begin{aligned} f(\omega, t, w, \alpha) &= r(\omega, t)w + \alpha' \mu^R(\omega, t), \\ (w, \alpha) &\in K \end{aligned} \quad (8)$$

Example 2 Different Borrowing and Lending Rates. Extending Example 1, if b is a strictly positive process and money-market lending and borrowing occur at the rates r_t and $r_t + b_t$, respectively, then

$$\begin{aligned} f(\omega, t, w, \alpha) &= r(\omega, t)w + \mu^R(\omega, t)' \alpha - b(\omega, t) \\ &\quad \times (\mathbf{1}' \alpha - w)^+, \quad (w, \alpha) \in K \end{aligned} \quad (9)$$

For a related analysis, see Appendix B of [6].

General Solution Method

The agent's problem is to choose an optimal consumption plan: a feasible c such that $U(c) \geq U(\tilde{c})$

for all other feasible consumption plans $\tilde{c}$. We first show that optimality of c is essentially equivalent to the utility supergradient density of U at c satisfying the conditions for a state-price density, and then characterize these density equations in terms of the utility and wealth aggregators defined above. The resulting first-order conditions satisfy a constrained forward-backward stochastic differential equation (FBSDE) system.

Given the feasible consumption plan c , the process $\pi \in \mathcal{H}$ is a *state-price density* at c if

$$\begin{aligned} (\pi|x) &\leq 0 \\ \text{for all } x \text{ such that } c+x &\text{ is a} \\ \text{feasible consumption plan} \end{aligned} \quad (10)$$

We can interpret $(\pi|x)$ as the net present value of the cash flow x , which must be nonpositive for any feasible (i.e., affordable) incremental cash flow.

The process $\pi \in \mathcal{H}$ is a *supergradient density* of U_0 at c if

$$\begin{aligned} U_0(c+x) &\leq U_0(c) + (\pi|x) \\ \text{for all } x \text{ such that } c+x &\in \mathcal{C} \end{aligned} \quad (11)$$

and a *utility gradient density* of U_0 at c if

$$\begin{aligned} (\pi|x) &= \lim_{\alpha \downarrow 0} \frac{U_0(c+\alpha x) - U_0(c)}{\alpha} \quad \text{for all } x \text{ such} \\ \text{that } c+\alpha x &\in \mathcal{C} \text{ for some } \alpha > 0 \end{aligned} \quad (12)$$

If π is a supergradient density of U_0 at c and the utility gradient of U_0 at c exists, then the utility gradient density is π .

The general optimality result follows.

Proposition 1 *Suppose that (c, W, ϕ) is a feasible plan. If $\pi \in \mathcal{H}$ is both a supergradient density of U_0 at c and a state-price density at c , then the plan (c, W, ϕ) is optimal. Conversely, if the plan (c, W, ϕ) is optimal and $\pi \in \mathcal{H}$ is a utility gradient density of U_0 at c , then π is a state-price density at c .*

To apply Proposition 1, we obtain the dynamics of the utility supergradient and state-price densities corresponding to the utility and market models, as discussed in the sections Recursive Preferences and Markets and the Wealth Equation. Both depend on the feasible reference plan (c, W, ϕ) and are expressed

in terms of the differential or superdifferential (in the absence of differentiability or in the presence of constraints) of the corresponding aggregator.

The *superdifferential* of $f(t, \cdot)$ at (ω, t, w, α) relative to the constraint set K is the set $\partial f(\omega, t, w, \alpha)$ of all pairs $(d_w, d_\phi) \in \mathbb{R}^{1+m}$ such that

$$\begin{aligned} f(\omega, t, \tilde{w}, \tilde{\alpha}) - f(\omega, t, w, \alpha) &\leq d_w(\tilde{w} - w) \\ + d'_\phi(\tilde{\alpha} - \alpha) &\quad \text{for all } (\tilde{w}, \tilde{\alpha}) \in K \end{aligned} \quad (13)$$

Sufficient conditions for a state-price density follow.^c

Proposition 2 *Suppose that (c, W, ϕ) is feasible and $\pi \in \mathcal{H}_{++}$ satisfies*

$$\frac{d\pi_t}{\pi_t} = -\zeta_t dt - \eta'_t dB_t, \quad (\zeta_t, \sigma_t^{R'} \eta_t) \in \partial f(t, W_t, \phi_t) \quad (14)$$

and $\pi W \in \mathcal{S}_1$. Then π is a state-price density at c .

The process η is often called the *market price of risk*, with η_t^i representing the time- t shadow incremental expected wealth return per unit additional exposure to dB_t^i . The drift term ζ represents the shadow incremental return per unit wealth. In the case of a linear budget equation (8) and $K = \mathbb{R}^{1+m}$ (no constraints but possibly incomplete markets), we obtain the standard result $\zeta_t = r_t$ and $\mu_t^R = \sigma_t^{R'} \eta_t$.

Example 3 Collateral Constraint. Suppose that there is a single risky asset ($m = 1$), and, as in Example 1, $f(\omega, t, w, \alpha) = r(\omega, t)w + \mu^R(\omega, t)\alpha$. We consider an agent who faces the collateral constraint:

$$K = \{(w, \alpha) \in \mathbb{R}^2 : w \geq \varrho|\alpha|\} \quad (15)$$

for some $\varrho \in (0, 1)$. Then condition $(\zeta, \sigma^{R'} \eta) \in \partial f(W, \phi)$ is equivalent to the following restrictions:

$$\begin{aligned} \delta_t &= \zeta_t - r_t \geq 0, \quad \varepsilon_t = \mu_t^R - \Theta_t \in [-\varrho\delta_t, \varrho\delta_t] \\ (\phi_t > 0 &\Rightarrow \varepsilon_t = \varrho\delta_t), \quad (\phi_t < 0 \Rightarrow \varepsilon_t = -\varrho\delta_t), \\ (W_t > \varrho|\phi_t| &\Rightarrow \delta_t = 0) \end{aligned} \quad (16)$$

Papers analyzing collateral constraints in a Brownian setting and additive utility include [5, 16].

Assuming differentiability of the utility aggregator F (nondifferentiability is accommodated by replacing

the differential with a superdifferential defined as for f), we now provide sufficient conditions for a utility supergradient density.

Proposition 3 *Suppose that $c \in \mathcal{C}$, (U, Σ) solves BSDE (5), $\pi \in \mathcal{H}_{++}$ satisfies*

$$\pi_t = \mathcal{E}_t F_c(t, c_t, U_t, \Sigma_t) \quad (17)$$

where

$$\begin{aligned} \frac{d\mathcal{E}_t}{\mathcal{E}_t} &= F_U(t, c_t, U_t, \Sigma_t)dt + \\ &F_\Sigma(t, c_t, U_t, \Sigma_t)'dB_t, \quad \mathcal{E}_0 = 1 \end{aligned} \quad (18)$$

and $\mathcal{E}U \in \mathcal{S}_1$. Then, π is a utility gradient density of U_0 at c .

The supergradient density expression (17) is consistent with the calculations of Skiadas [2], Duffie and Skiadas [9], Chen and Epstein [10], and El_Karoui *et al.* [21]. All these papers assume Lipschitz-growth conditions that are violated in our setting.

We now apply Proposition 1 to characterize the first-order conditions. A key role in the solution is played by the strictly positive process

$$\lambda_t = F_c(t, c_t, U_t, \Sigma_t) \quad (19)$$

computed at the optimum, which represents the derivative of time- t optimal utility with respect to time- t wealth (as in the familiar envelope result). We solve for μ^λ and σ^λ in the Ito expansion

$$\frac{d\lambda_t}{\lambda_t} = \mu_t^\lambda dt + \sigma_t^{\lambda'} dB_t \quad (20)$$

by applying Ito's lemma to the utility gradient density, $\pi_t = \mathcal{E}_t \lambda_t$, and matching coefficients with those of the state-price density in Proposition 2. Having solved for λ , invert equation (19) to express the consumption plan c as

$$c_t = \mathcal{I}(t, \lambda_t, U_t, \Sigma_t) \quad (21)$$

where the function $\mathcal{I} : \Omega \times [0, T] \times (0, \infty) \times \mathbb{R}^{d+1} \rightarrow \mathbb{R}$ is defined implicitly through the following equation:

$$F_c(t, \mathcal{I}(t, y, U, \Sigma), U, \Sigma) = y, \quad y \in (0, \infty) \quad (22)$$

Combining the dynamics of λ with the utility BSDE (5), the budget equation (7), and the state-pricing restriction of Proposition 2, we obtain the

optimality conditions in the form of a constrained FBSDE system:

$$\begin{aligned} dU &= -F(\mathcal{I}(\lambda, U, \Sigma), U, \Sigma)dt + \Sigma' dB, \\ U_T &= F(T, W_T + e_T) \\ \frac{d\lambda_t}{\lambda_t} &= -(\zeta + F_U + \sigma^{\lambda'} F_\Sigma)dt + \sigma^{\lambda'} dB, \\ \lambda_T &= F_c(T, W_T + e_T) \\ dW &= (f(W, \phi) + e - \mathcal{I}(\lambda, U, \Sigma))dt + \phi' \sigma_t^{R'} dB_t, \\ W_0 &= w_0 \\ (\zeta, -\sigma^{R'}(F_\Sigma + \sigma^\lambda)) &\in \partial f(W, \phi), \\ (\phi, W) &\in K \end{aligned} \quad (23)$$

Given a solution $(U, \Sigma, \lambda, \sigma^\lambda, W, \phi)$ and suitable integrability assumptions (to satisfy Propositions 1–3), then c in equation (21) defines an optimal consumption plan.

Scale and Translation-invariant Solutions

The first-order conditions significantly simplify when utility and wealth dynamics fall into either the scale or translation-invariant classes. The scale-invariant, or homothetic, class exhibits homogeneity of degree one in consumption (when in certainty equivalent form) and includes, as special cases, homothetic Duffie–Epstein utility and additive power and log utility. The translation-invariant class exhibits quasilinearity with respect to a reference consumption stream and generalizes additive exponential utility. In both cases, the FBSDE of the first-order conditions uncouples into a single pure backward equation for λ and a pure forward equation for wealth.

Scale-invariant Class

We assume that consumption is strictly positive, and the aggregator $F(\omega, t, \cdot)$ is homogeneous of degree one, allowing the representation

$$\begin{aligned} F(\omega, t, c, U, \Sigma) &= UG\left(\omega, t, \frac{c}{U}, \frac{\Sigma}{U}\right), \\ F(T, c) &= c \end{aligned} \quad (24)$$

It is easy to confirm that utility is therefore homogeneous of degree one in consumption:

$$U(kc) = kU(c) \quad \text{for all } k \in \mathbb{R}_+ \text{ and } c \in \mathcal{C} \quad (25)$$

Defining $\sigma_t^U = \Sigma_t/U_t$, the BSDE (5) is equivalent to

$$\frac{dU_t}{U_t} = -G(t, c_t/U_t, \sigma_t^U)dt + \sigma_t^{U'}dB_t, \quad U_T = c_T \quad (26)$$

Example 4 Schroder and Skiadas [19] show that the quasi-quadratic aggregator

$$G(\omega, t, x, \sigma) = g(\omega, t, x) - \frac{1}{2}\Sigma'Q(\omega, t)\Sigma \quad (27)$$

where Q is positive definite for all (ω, t) , is particularly tractable, while allowing the modeling of source-dependent second-order risk aversion through Q . The continuous-time version of Epstein and Zin [11] is the special case with $Q = \gamma I$, for some constant $\gamma > 0$, and

$$g(\omega, t, x) = \alpha + \beta \frac{x^{1-\eta} - 1}{1-\eta} \quad (28)$$

for constants α and $\eta, \beta > 0$. Additive utility corresponds to $\gamma = \eta$ (the coefficient of relative risk aversion is equal to the inverse of the elasticity of intertemporal substitution).

On the markets side, we assume that wealth is strictly positive; the endowment process, e , is zero; constraints are on investment proportions, $\phi_t/W_t \in K^1$, for some convex set $K^1 \subseteq \mathbb{R}^m$; and the wealth aggregator $f(\omega, t, \cdot)$ is homogeneous of degree one. Letting $\psi_t = \phi_t/W_t$ denote the vector of investment proportions, and defining $f^1(t, \cdot) = f(t, 1, \cdot)$, the budget equation (7) becomes

$$\begin{aligned} \frac{dW_t}{W_t} &= \left(f^1(t, \psi_t) - \frac{c_t}{W_t} \right) dt + \psi_t' \sigma_t^{R'} dB_t, \\ W_0 &= w_0, \quad c_T = W_T, \quad \psi_t \in K^1 \end{aligned} \quad (29)$$

(in the linear budget constraint case of Example 1, we have $f^1(t, \psi_t) = r_t + \psi_t' \mu_t^R$).

The state-price density condition $(\zeta_t, \sigma_t^{R'} \eta_t) \in \partial f(t, W_t, \phi_t)$ is then equivalent to

$$\zeta_t = f^1(t, \psi_t) - \psi_t' \sigma_t^{R'} \eta_t \quad \text{and} \quad \sigma_t^{R'} \eta_t \in \partial f^1(t, \psi_t) \quad (30)$$

The scale-invariance properties imply that at the optimum utility is proportional to wealth:

$$U_t = \lambda_t W_t \quad (31)$$

and therefore $\sigma_t^U = \sigma_t^\lambda + \sigma_t^R \psi_t$. Recalling $\lambda_t = G_c(t, c_t/U_t, \sigma_t^U)$, we define the inverse function $\mathcal{I}^G(\cdot)$ analogously to equation (22) to obtain $c_t/U_t = \mathcal{I}^G(t, \lambda_t, \sigma_t^U)$. Defining the dual function of G^*

$$G^*(t, \lambda, \sigma) = G(t, \mathcal{I}^G(t, \lambda, \sigma), \sigma) - \mathcal{I}^G(t, \lambda, \sigma)\lambda \quad (32)$$

we obtain the first-order conditions (necessary and sufficient) as a constrained backward equation for λ (independent of wealth):

$$\begin{aligned} \frac{d\lambda}{\lambda_-} &= - \left(G^*(\lambda, \sigma^\lambda + \sigma^R \psi) + f^1(\psi) \right. \\ &\quad \left. + \psi' \sigma^{R'} \sigma^\lambda \right) dt + \sigma_t^{\lambda'} dB_t, \quad \lambda_T = 1, \\ &\quad - \sigma^R (G_\sigma + \sigma^\lambda) \in \partial f^1(\psi) \end{aligned} \quad (33)$$

Given a solution $(\lambda, \sigma^\lambda, \psi)$ and sufficient regularity, then $c_t/W_t = \lambda_t \mathcal{I}^G(t, \lambda, \sigma)$ is substituted into the wealth equation to complete the solution.

Translation-invariant Class

We allow consumption to take any value in $\mathbb{R}$ and fix some strictly positive and bounded reference consumption plan $\gamma \in \mathcal{H}$. The aggregator is assumed to satisfy

$$\begin{aligned} F(\omega, t, c, U, \Sigma) &= G\left(\omega, t, \frac{c}{\gamma(\omega, t)} - U, \Sigma\right), \\ F(\omega, T, c) &= \frac{c}{\gamma(\omega, T)} \end{aligned} \quad (34)$$

which implies that U is quasilinear with respect to γ :

$$U(c + k\gamma) = U(c) + k \quad \text{for all } k \in \mathbb{R} \text{ and } c \in \mathcal{C} \quad (35)$$

Example 5 Additive exponential utility corresponds to

$$G(\omega, t, x, \Sigma) = \beta(\omega, t) - \exp(-x) - \frac{1}{2}\Sigma' \Sigma \quad (36)$$

This follows because the ordinally equivalent utility $V_t = -\exp(-U_t)$ satisfies (under suitable integrability restrictions)

$$V_t = E_t \left[\int_t^T -\exp\left(-\int_t^s \beta_u du - \frac{c_s}{\gamma_s}\right) ds \right]$$

$$- \exp \left(- \int_t^T \beta_u du - \frac{c_T}{\gamma_T} \right) \Big] \quad (37)$$

On the markets side, we assume that the reference consumption stream γ is part of the feasible plan $(\gamma, \Gamma, \Gamma\kappa)$:

$$\frac{d\Gamma_t}{\Gamma_t} = \left(\mu_t^\kappa - \frac{\gamma_t}{\Gamma_t} \right) dt + \kappa' \sigma_t^{R'} dB_t, \quad \Gamma_T = \gamma_T \quad (38)$$

That is, Γ is the price of a fund paying dividend process γ ; $\kappa \in \mathbb{R}^m$ represents the investment proportions of the fund; and μ^κ is the fund's instantaneous expected return process.

For any $(w, \alpha) \in K$, we assume $(w + v, \alpha + v\kappa) \in K$ and $f(\omega, t, w + v, \alpha + v\kappa) = f(\omega, t, w, \alpha) + v\mu^\kappa(\omega, t)$ for all $v \in \mathbb{R}$. That is, trading in the portfolio κ is unrestricted and earns instantaneous expected return μ^κ regardless of the agent's plan. For example, under the linear budget equation (Example 1), we have $\mu^\kappa = r + \kappa' \mu^R$.

Defining the zero-wealth constraint set, aggregator, and portfolio and consumption processes

$$\begin{aligned} K^0 &= \{ \alpha : (0, \alpha) \in K \}, \\ f^0(\omega, t, \alpha) &= f(\omega, t, 0, \alpha), \\ \phi_t^0 &= \phi_t - W_t \kappa, \\ c_t^0 &= c_t - W_t \frac{\gamma_t}{\Gamma_t} \end{aligned} \quad (39)$$

the budget equation (7) is equivalent to

$$\begin{aligned} dW_t &= W_t \frac{d\Gamma_t}{\Gamma_t} + (f^0(t, \phi_t^0) + e_t - c_t^0) dt \\ &\quad + \phi_t^{0'} \sigma_t^{R'} dB_t, \\ c_T^0 &= e_T, \quad \phi_t^0 \in K^0 \end{aligned} \quad (40)$$

At the optimum, the quasi-linearity of utility and markets implies that there are two components to consumption and trading. The pair (c^0, ϕ^0) depends on the investment opportunity set and the endowment, but is independent of W . All incremental financial wealth is invested in the portfolio κ , and the resulting dividend stream rate γ is consumed; therefore, $(c - c^0, \phi - \phi^0)$ depend only on W and the dividend yield

γ/Γ . Utility and marginal utility of wealth processes satisfy

$$U_t = \frac{1}{\Gamma_t} (Y_t + W_t), \quad \lambda_t = \frac{1}{\Gamma_t} \quad (41)$$

where (Y, ϕ^0) is determined by a constrained backward SDE, given below, that is independent of financial wealth.

Defining the superdifferential notation ∂f^0 analogously to ∂f , the state-price density condition $(\zeta, \sigma^{R'} \eta) \in \partial f(W, \phi)$ is equivalent to $\zeta = \mu^\kappa - \kappa' \sigma^{R'} \eta$ and $\sigma^{R'} \eta \in \partial f^0(\phi^0)$. Defining the inverse and dual functions $\mathcal{X}, G^* : \Omega \times [0, T] \times \mathbb{R}^{d+1} \rightarrow \mathbb{R}$ by

$$\begin{aligned} G_x(\omega, t, \mathcal{X}(\omega, t, y, \Sigma), \Sigma) &= y, \\ G^*(\omega, t, y, \Sigma) &= G(\omega, t, \mathcal{X}(\omega, t, y, \Sigma), \Sigma) \\ &\quad - y \mathcal{X}(\omega, t, y, \Sigma) \end{aligned} \quad (42)$$

the processes (Y, σ^Y, ϕ^0) satisfy

$$\begin{aligned} dY &= - (e - Y\mu^\kappa + f^0(\phi^0) + \Gamma G^*(\delta, \Sigma) \\ &\quad - \Gamma \kappa' \sigma^{R'} \Sigma) dt + \sigma^{Y'} dB, \quad Y_T = e_T \\ \Sigma &= \frac{\sigma^Y + (\phi^0 - \kappa Y)' \sigma^R}{\Gamma}, \\ -\sigma^{R'} (G_\Sigma - \sigma^R \kappa) &\in \partial f^0(\phi^0), \quad \phi^0 \in K^0 \end{aligned} \quad (43)$$

Given the solution (Y, σ^Y, ϕ^0) and sufficient regularity, the optimal wealth-independent component of consumption is

$$c_t^0 = \frac{\gamma_t}{\Gamma_t} Y_t + \gamma_t \mathcal{X} \left(t, \frac{\gamma_t}{\Gamma_t}, \Sigma_t \right) \quad \text{and} \quad c_T^0 = e_T \quad (44)$$

Substituting (c^0, ϕ^0) into the budget equation (40), the optimal plan is $(c^0 + W\gamma/\Gamma, W, \phi^0 + W\kappa)$.

Acknowledgments

I am grateful to Costis Skiadas for many fruitful years of joint research, on which this article is based.

End Notes

^aSee also [25], which develops the discrete-time counterpart of (5), and [24], which develops the continuous-time formulations of other notions of ambiguity aversion.

^bWe define arbitrage in the constrained case as a feasible incremental cash flow (given the current portfolio of the agent) that is nonnegative and nonzero.

^cWith some additional mild technical conditions, Schroder and Skiadas [20] show the necessity of the state-price characterization for the market settings in the scale and translation-invariant classes, which are discussed below in the text.

Risk Aversion

An agent is risk averse if he/she dislikes the actions whose outcomes are not certain. In the following, only actions with one-dimensional final outcomes, for example, sums of money, are taken into consideration. To define risk aversion, it is necessary that a probability is associated to every possible consequence, that is, that the actions can be represented as lotteries. A lottery is *simple* if all possible consequences are final outcomes (sums of money) and it is *compound* if other lotteries are included among its consequences. An outcome coincides with a *degenerate* lottery, that is, the lottery that generates it with probability one.

Formally, a decision-making situation under risk is represented by the quintuple $\langle S; 2^S; p; X; \mathcal{L} \rangle$, where S is a set of states of the nature; 2^S is its power set (i.e., the set of all subsets of S , the empty set included); p is a probability distribution on 2^S ; X is a set of outcomes (with $X \subseteq \mathbb{R}$ if they are one-dimensional); and $\mathcal{L}$ is the set of lotteries. A simple lottery is represented by $\ell = (x(E), p(E))_{E \in \text{Part}(S)}$, where outcomes and probabilities are associated with the events $E \subseteq S$ that form a partition $\text{Part}(S)$ of S ; a compound lottery by $\ell = (\ell(E), p(E))_{E \in \text{Part}(S)}$, with $\ell(E) = (\ell'(E'), p(E'))_{E' \in \text{Part}(E)}$; and a degenerate lottery by $\ell = (x, 1)$. A simple lottery is also represented by the cumulative probability function $F : X \rightarrow [0, 1]$, where $F(\cdot)$ is a nondecreasing function with range $[0, 1]$, and, if S is finite, that is, $S = \{s_1, \dots, s_m\}$, by $\ell = (x_i, p_i)_{i=1}^n$, where $p_i = p(E_i)$ with $E_i = \{s_h \in S : x(s_h) = x_i\}$. An agent in a risky situation is a system of preferences $\langle \mathcal{L}, \succsim \rangle$ over the set of lotteries. Let $\langle \mathcal{L}, \succsim \rangle$ be regular (i.e., complete and transitive) and continuous. Moreover, let it be strongly monotone with respect to degenerate lotteries, that is, $(x, 1) \succ (x', 1)$ if $x > x'$. Then, preferences can be represented by a utility function $U : \mathcal{L} \rightarrow \mathbb{R}$, that is, such that $U(\ell) \geq U(\ell')$ if and only if $\ell \succsim \ell'$. This function is not necessarily the expected utility function. However, if the expected utility model is introduced, then every lottery is equivalent to a simple lottery because of the *compound lottery principle* (implied by expected utility), according to which any compound lottery is indifferent to the simple (or reduced) lottery that associates to each final outcome its compound probability, and preferences are represented by the expected utility function,

which is represented by $EU(\ell) = \int_{x \in X} u(x) dF(x)$ if $F(\cdot)$ is differentiable or $EU(\ell) = \sum_{i=1}^n p_i u(x_i)$ if the lottery is finite. The von Neumann–Morgenstern (or Bernoulli) utility function $u : X \rightarrow \mathbb{R}$ represents the preferences over the set of degenerate lotteries, that is, over the set of outcomes.

Definition 1 (*Expected Value*). *The expected value of a lottery $\ell \in \mathcal{L}$ is $EV(\ell) = \int_{x \in X} x dF(x)$ or, if the lottery is finite, $EV(\ell) = \sum_{i=1}^n p_i x_i$ and the function $EV : \mathcal{L} \rightarrow X$ is the expected value function.*

Definition 2 (*Certainty Equivalent*). *The certainty equivalent $CE(\ell)$ of a lottery $\ell \in \mathcal{L}$ is the outcome for which the individual is indifferent between this outcome and the lottery, that is, $(CE(\ell), 1) \sim \ell$, where $(CE(\ell), 1)$ is the degenerate lottery with outcome $CE(\ell)$. Having $U(\ell) = u(CE(\ell))$, the certainty equivalent function is $CE(\ell) = u^{-1}(U(\ell))$. If the system of preferences $\langle \mathcal{L}, \succsim \rangle$ can be represented by an expected utility function, then $CE(\ell) = u^{-1}(EU(\ell))$.*

Proposition 1 (*Existence and Uniqueness of the Certainty Equivalent*). *Let us assume that the set of outcomes is compact, that is, $X = [\underline{x}, \bar{x}]$ and the system of preferences $\langle \mathcal{L}, \succsim \rangle$ is regular (i.e., complete and transitive), continuous and such that $(\bar{x}, 1) \succsim \ell \succsim (\underline{x}, 1)$ for every $\ell \in \mathcal{L}$. Then, there exists one and only one certainty equivalent $CE(\ell) \in X$ for every $\ell \in \mathcal{L}$.*

The following discussion on the notion of risk aversion refers, for the sake of simplicity, to finite simple lotteries on a compact set of outcomes, where not specified differently.

Global Risk Aversion

Definition 3 (*Risk Premium and Global Risk Aversion*). *The risk premium $RP(\ell)$ of a lottery is the maximum sum of money that the agent is willing to pay to get the expected value of the lottery in place of the lottery. Therefore,*

$$RP(\ell) = EV(\ell) - CE(\ell) \quad (1)$$

since the conditions $(EV(\ell) - RP(\ell), 1) \sim \ell$ and $\ell \sim (CE(\ell), 1)$ imply $EV(\ell) - RP(\ell) = CE(\ell)$. The agent denotes (global) *risk aversion* if his/her

system of preferences $\langle \mathcal{L}, \succsim \rangle$ requires $CE(\ell) \leq EV(\ell)$, so $RP(\ell) \geq 0$, for every $\ell \in \mathcal{L}$. The agent is risk loving if $RP(\ell) \leq 0$ and risk neutral if $RP(\ell) = 0$. He/she is strictly risk averse if $RP(\ell) > 0$ for every nondegenerate $\ell \in \mathcal{L}$ (strictly risk loving if $RP(\ell) < 0$). An agent is globally neither risk averse nor risk loving if there is a pair $\ell, \ell' \in \mathcal{L}$ for which $RP(\ell) > 0$ and $RP(\ell') < 0$.

Proposition 2 [5]. *Let us introduce the set of the lotteries that are not preferred to the certain outcome x and the set of lotteries that have an expected value not higher than x , that is,*

$$\begin{aligned} G(x) &= \{\ell \in \mathcal{L} : CE(\ell) \leq x\}, \\ H(x) &= \{\ell \in \mathcal{L} : EV(\ell) \leq x\} \end{aligned} \quad (2)$$

The agent is risk averse if and only if $H(x) \subseteq G(x)$ for every $x \in X$, risk loving if and only if $H(x) \supseteq G(x)$, and risk neutral if and only if $H(x) = G(x)$.

In the Hirshleifer–Yaari diagram, where simple lotteries with only two possible outcomes with given probabilities are represented, the certainty equivalent of a lottery $\ell^* = (x_1^*, p; x_2^*, 1 - p)$ is, by definition, determined as the intersection of the 45° line and the corresponding indifference curve. Therefore, the certainty equivalent is equal to the coordinates of this point. Moreover, the expected value of the same lottery is equal to the coordinates of the point where the 45° line intersects the expected value line (described by the equation $px_1 + (1 - p)x_2 = EV(\ell^*) = px_1^* + (1 - p)x_2^*$). This line passes through ℓ^* and has the slope equal to $-\frac{p}{1-p}$. Thus, the agent is risk averse if the first intersection point is not above the second one, as shown in Figures 1 and 2.

Proposition 2 indicates that risk aversion implies $H(CE(\ell^*)) \subseteq G(CE(\ell^*))$. It means that the indifference curve and the expected value line passing through the same point on the 45° line do not cross and that the indifference curve is to the north-east with respect to the expected value line.

Proposition 3 *If the expected utility model applies, then the agent is risk averse if and only if his/her von Neumann–Morgenstern utility function $u : X \rightarrow \mathbb{R}$ is concave, risk loving if and only if it is convex, and risk neutral if and only if it is a linear.*

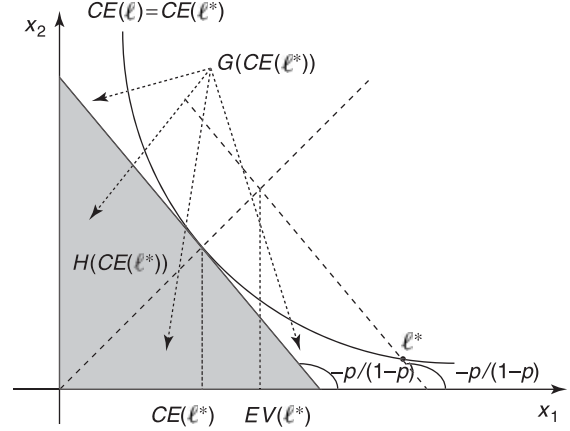

Figure 1 Indifference curve of a risk averse expected utility agent

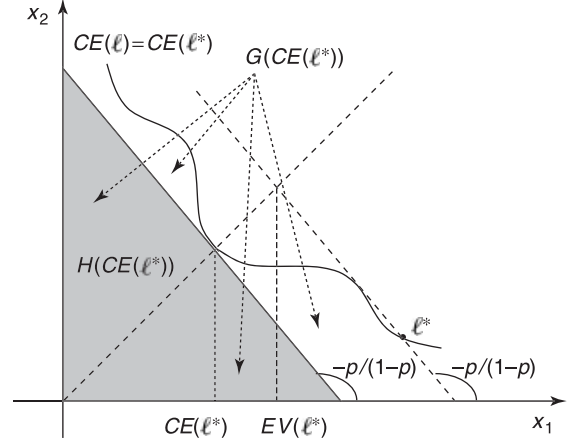

Figure 2 Indifference curve of a risk averse nonexpected utility agent

The inequality $\sum_{i=1}^n p_i u(x_i) \leq u(\sum_{i=1}^n p_i x_i)$, which is called the *Jensen inequality*, is a definition of concavity and is equivalent to $EU(\ell) \leq u(EV(\ell))$.

In Figure 3 we can see how the concavity of the function $u(\cdot)$ implies risk aversion. The expected value, expected utility, and certainty equivalent are represented for the lottery $\ell = (x_1, 0.5; x_2, 0.5)$.

The concavity of the von Neumann–Morgenstern function $u(\cdot)$ implies the concavity of the expected utility function with respect to the outcomes. That is, if $u(\lambda x_i + (1 - \lambda)x_i') \geq \lambda u(x_i) + (1 - \lambda)u(x_i')$ for every pair $x_i, x_i' \in X$ and every $\lambda \in [0, 1]$,

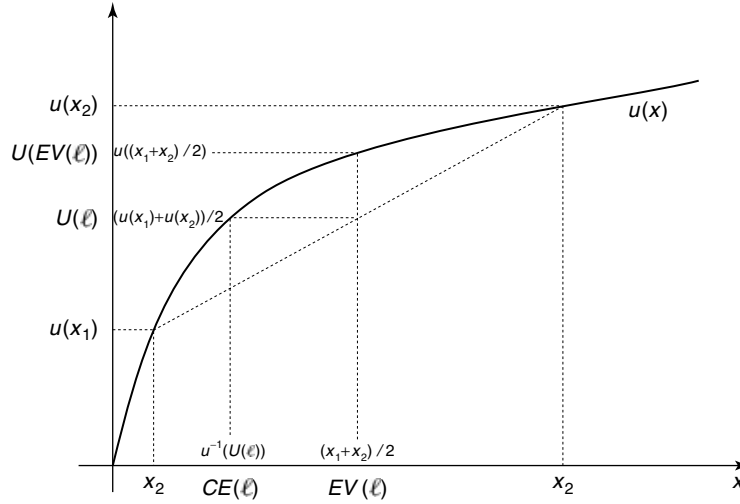

Figure 3 Risk aversion and concavity of utility function

then $EU(\ell'') \geq \lambda EU(\ell) + (1 - \lambda)EU(\ell')$ for every $\lambda \in [0, 1]$ and every triplet $\ell, \ell', \ell'' \in \mathcal{L}$, with $\ell = (x_i, p_i)_{i=1}^n$, $\ell' = (x'_i, p_i)_{i=1}^n$ and $\ell'' = (x''_i, p_i)_{i=1}^n$. Thus, if the agent is risk averse and the expected utility theory holds, the function $EU(\cdot)$ is concave (and, all the more so, quasiconcave) with respect to the outcomes. Consequently, the indifference curves in the Hirshleifer–Yaari diagram are convex (as described in Figure 1, but not in Figure 2, which can represent an agent who is risk averse but does not maximize expected utility).

Proposition 4 [5]. *The agent is risk averse if the certainty equivalent function $CE : \mathcal{L} \rightarrow X$ is convex with respect to the probabilities. The agent is risk loving if it is concave and risk neutral if it is linear.*

The condition stated in Proposition 4 for risk aversion is sufficient, but not necessary, nor is it necessary that the certainty equivalent function $CE(\cdot)$ is quasi-convex with respect to the probabilities. However, if the expected utility theory holds and there is risk aversion, then the certainty equivalent function is convex with respect to the probabilities: in fact, in such a case, we have $CE(\ell) = u^{-1}(\sum_{i=1}^n p_i u(x_i))$, where function $u(\cdot)$ is increasing and concave and function $u^{-1}(\cdot)$ is increasing and convex.

Definition 4 (Comparison of Risk Aversion across Agents). *An agent A is more risk averse than agent*

B if their systems of preferences $\langle \mathcal{L}, \succsim^A \rangle$ and $\langle \mathcal{L}, \succsim^B \rangle$ give $CE_A(\ell) \leq CE_B(\ell)$ for every $\ell \in \mathcal{L}$.

In the Hirshleifer–Yaari diagram, this definition implies that the indifference curves of the agents that go through the same point on the 45° line do not cross and that the indifference curve of the more risk averse agent is to the north-east with respect to the indifference curve of the less risk averse agent, as shown in Figure 4.

Proposition 5 [7]. *If agent A is more risk averse than agent B and the expected utility model applies,*

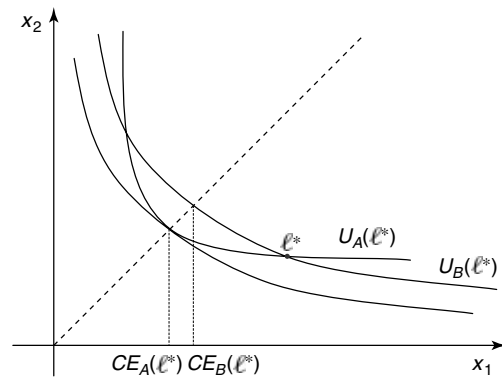

Figure 4 Indifference curves of two agents of whom one is more risk averse than the other

then the von Neumann–Morgenstern utility function $u_A(\cdot)$ is a concave transformation of $u_B(\cdot)$. That is, there exists an increasing and concave function $g : \mathbb{R} \rightarrow \mathbb{R}$ such that $u_A(x) = g(u_B(x))$ for every $x \in X$.

Local Risk Aversion

Till now, we considered *global risk aversion*, that is, the relationship $CE(\ell) \leq EV(\ell)$ was introduced for every lottery $\ell \in \mathcal{L}$. Now, let us consider *local risk aversion*, by taking into account only small lotteries, that is, the lotteries that have only little differences in consequences. For this purpose, we denote the lottery $(x + tx_i, p_i)_{i=1}^n$ with $x + t\ell$, where $\ell = (x_i, p_i)_{i=1}^n$.

Definition 5 (*Local Risk Aversion*). An agent is locally risk averse, if, for every $x \in X$ and $\ell \in \mathcal{L}$, there exists a $t^* > 0$ such that $CE(x + t\ell) \leq EV(x + t\ell)$ for all $t \in [0, t^*]$. Thus, if the certainty equivalent function can be derived, then the agent is locally risk averse if $\lim_{t \rightarrow 0} \frac{d}{dt} (EV(x + t\ell) - CE(x + t\ell)) > 0$ and only if $\lim_{t \rightarrow 0} \frac{d}{dt} (EV(x + t\ell) - CE(x + t\ell)) \geq 0$ for every $x \in X$ and $\ell \in \mathcal{L}$. By analogy, the definition holds with reversed inequality signs for the local risk loving.

Although the global risk aversion requires that in the Hirshleifer–Yaari diagram the indifference curve and the expected value line passing through some point on the 45° line do not cross and that the indifference curve is to the north-east with respect to the expected value line, this condition needs to be satisfied only in the vicinity of the 45° line for the local risk aversion.

Proposition 6 If the expected utility theory holds, then the agent is locally risk averse if and only if his/her von Neumann–Morgenstern utility function $u : X \rightarrow \mathbb{R}$ is concave. In other words, if the expected utility theory holds, then the conditions for local and global risk aversion (risk loving or neutrality) are the same.

Measure of the Risk Aversion

If the expected utility theory holds, then the local risk aversion can be measured by the concavity of the von Neumann–Morgenstern utility function $u(\cdot)$. However, the second derivative of the utility function

$u''(\cdot)$, which is a measure of its concavity, is not invariant to increasing linear transformations of $u(\cdot)$. An invariant measure is the *de Finetti–Arrow–Pratt coefficient of risk aversion* (due to de Finetti [3], Pratt [7], and Arrow [1]). This measure of (*absolute*) risk aversion is defined as

$$r(x) = -\frac{u''(x)}{u'(x)} \quad (3)$$

There also exists a measure of *relative risk aversion* $r_r(x) = -x \frac{u''(x)}{u'(x)}$, which is important in the case of multiplicative lotteries $\ell = (\alpha_i W, p_i)_{i=1}^n$.

The de Finetti–Arrow–Pratt measure can be justified in relation to the local risk premium, which is (by Definition 3)

$$\begin{aligned} RP(x + t\ell) &= EV(x + t\ell) - CE(x + t\ell) \\ &= x + tEV(\ell) \\ &\quad - u^{-1} \left(\sum_{i=1}^n p_i u(x + tx_i) \right) \end{aligned} \quad (4)$$

Then, assuming that this function is differentiable with respect to t , we get $RP(x) = 0$, $\left. \frac{\partial RP(x + t\ell)}{\partial t} \right|_{t=0} = 0$ and $\left. \frac{\partial^2 RP(x + t\ell)}{\partial t^2} \right|_{t=0} = -\frac{u''(x)}{u'(x)} \sigma^2(\ell)$. Therefore, in the neighborhood of the certain outcome x , the risk premium is proportional to the de Finetti–Arrow–Pratt measure. Nevertheless, the fact that only the second derivative of the risk premium can be different from zero at $t = 0$, while the first derivative is always equal to zero, means that the expected utility theory allows only for local risk aversion of the second order, while that of the first order is zero. Other theories (e.g., *rank-dependent expected utility*, which is discussed later) also allow for the risk aversion of the first order and can, as a result, describe the preferences that indicate more relevant types of aversion to risk (like the one presented in Allais paradox) than the risk aversion admitted by the expected utility theory and measured by the de Finetti–Arrow–Pratt index.

Local risk aversion in the Hirshleifer–Yaari diagram is linked to the curvature of indifference curves at the point where they intersect the 45° line. In other words, it is linked to the value of the second derivative $x_2''(x_1)$ at $x_1 = x$, where

the function $x_2(x_1)$ that represents the indifference curve is implicitly defined by the condition $CE(x_1, x_2) = x$. Then, if the expected utility theory holds, we get $x_2(x) = x$, $x_2'(x) = -\frac{p}{1-p}$ and $x_2''(x) = -\frac{p}{(1-p)^2} \frac{u''(x)}{u'(x)}$, that is, the curvature of the indifference curves along the 45° line is proportional to the de Finetti–Arrow–Pratt measure of risk aversion.

The dependence of the de Finetti–Arrow–Pratt index $r(x)$ on x defines the decreasing absolute risk aversion if $r'(x) < 0$ (increasing if $r'(x) > 0$), as well as, with regard to $r_r(x)$, the decreasing relative risk aversion if $r_r'(x) < 0$ (increasing if $r_r'(x) > 0$).

Aversion Toward Increases in Risk

Risk aversion can also be analyzed taking into account the riskiness of lotteries, that is, considering preference for less risky lotteries. However, there does not exist a unique definition of riskiness according to which lotteries can be ordered. In the following, only two definitions of riskiness are examined. Both introduce a partial ordering criterion.

1. The first definition refers to *mean preserving spreads* (introduced by Rothschild and Stiglitz [10]). A lottery $\ell = (x_i, p_i)_{i=1}^n$ is not less risky than lottery $\ell^* = (x_i^*, p_i^*)_{i=1}^n$ if ℓ can be obtained from ℓ^* by mean preserving spreads. That is, if $EV(\ell) = EV(\ell^*)$, $x_i = x_i^*$ for every $i = 1, \dots, n$ and $p_i = p_i^*$ for every $i = 1, \dots, n$ except for three outcomes $x_a > x_b > x_c$, for which we have $p_a \geq p_a^*$, $p_b \leq p_b^*$, and $p_c \geq p_c^*$. For example, $\ell = (x_1, p_1; x_2, p_2; x_3, p_3)$ is not less risky than $\ell^* = (x_1, p_1^*; x_2, p_2^*; x_3, p_3^*)$ if $p_2 \leq p_2^*$, $p_1 = p_1^* + \frac{x_2 - x_3}{x_1 - x_3}(p_2^* - p_2)$, $p_3 = p_3^* + \frac{x_1 - x_2}{x_1 - x_3}(p_2^* - p_2)$, and $x_1 > x_2 > x_3$.

Definition 6 (*Aversion to Mean Preserving Spreads Increases in Risk*). An agent is averse to the increases in risk if $CE(\ell) \leq CE(\ell^*)$ for every pair of lotteries $\ell, \ell^* \in \mathcal{L}$ with ℓ not less risky than ℓ^* (according to mean preserving spreads).

Proposition 7 If an agent is averse to mean preserving spreads increases in risk, then he/she is also risk averse (for this reason, sometimes the aversion to mean preserving spreads increases in risk is

called *strong risk aversion* and the risk aversion as introduced in Definition 3 is called *weak risk aversion* [2]). To be precise, if $CE(\ell) \leq CE(\ell^*)$ for every pair $\ell, \ell^* \in \mathcal{L}$ with ℓ not less risky than ℓ^* (according to mean preserving spreads), then $CE(\ell) \leq EV(\ell)$ for every $\ell \in \mathcal{L}$.

Proposition 8 If the expected utility model applies, then there is aversion toward mean preserving spreads increases in risk if and only if the von Neumann–Morgenstern utility function $u : X \rightarrow \mathbb{R}$ is concave.

Note that the concavity of the utility function is a necessary and sufficient condition for both risk aversion and aversion to increases in risk (determined by mean preserving spreads). The equality of this condition holds in the case of expected utility theory. For other theories, we will generally have two different conditions (one for risk aversion and the other for the aversion to increases in risk).

An ordering of the lotteries according to their riskiness that is equivalent to the mean preserving spreads concept (for the lotteries that have equal expected value) is provided by the notion of the *second-order stochastic dominance*.

Definition 7 (*First-order Stochastic Dominance*). A lottery $\ell = (x_i, p_i)_{i=1}^n$, where $x_i > x_{i+1}$ for every $i = 1, \dots, n-1$, first order stochastically dominates lottery $\ell' = (x_i, p_i')_{i=1}^n$ if $\sum_{h=1}^i p_h \geq \sum_{h=1}^i p_h'$ (or, equivalently, $\sum_{h=i+1}^n p_h \leq \sum_{h=i+1}^n p_h'$) for every $i = 1, \dots, n-1$, that is, with respect to the cumulative probability functions (introduced earlier), if $F(x) \leq F'(x)$ for every $x \in X$.

First-order stochastic dominance means that probabilities of the better (worse) outcomes are higher (lower) in the dominant lottery than in the dominated lottery. It implies that $EV(\ell) \geq EV(\ell')$ and, also, $CE(\ell) \geq CE(\ell')$ for a rational agent.

Definition 8 (*Second-order Stochastic Dominance*). A lottery $\ell = (x_i, p_i)_{i=1}^n$, where $x_i > x_{i+1}$ for every $i = 1, \dots, n-1$, second order stochastically dominates lottery $\ell' = (x_i, p_i')_{i=1}^n$ if $D_j(\ell, \ell') = \sum_{i=j}^{n-1} (x_i - x_{i+1}) \sum_{h=1}^j (p_h - p_h') \geq 0$ for every $j = 1, \dots, n-1$, that is, with respect to the cumulative probability functions in the continuous case, if $\int_{\underline{x}}^x (F(t) - F'(t))dt \leq 0$ for every $x \in X = [\underline{x}, \bar{x}]$. The first-order

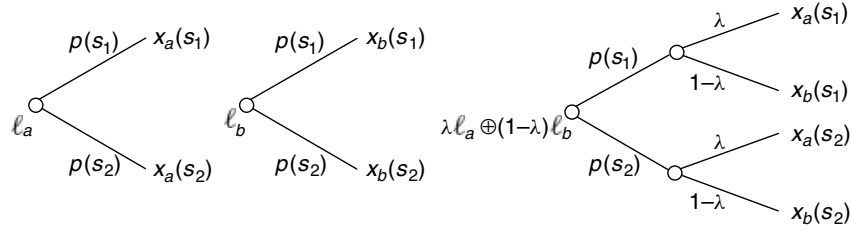

Figure 5 Probability mixture of two lotteries

stochastic dominance implies second-order stochastic dominance, but not vice versa.

Proposition 9 *Let two lotteries ℓ and ℓ' have the same expected value, so that $\sum_{i=1}^{n-1} (x_i - x_{i+1}) \sum_{h=1}^j (p_h - p'_h) = 0$. If the lottery ℓ' is more risky than ℓ (according to the mean preserving spreads criterion), then ℓ second-order stochastically dominates ℓ' . Conversely, if ℓ second-order stochastically dominates ℓ' , then ℓ' can be obtained from ℓ by a sequence of mean preserving spreads.*

The equivalence of the second-order stochastic dominance and mean preserving spreads for the lotteries with the same expected value implies that the same conditions that determine the aversion to the increases in risk (introduced by mean preserving spreads) also determine the aversion for the lotteries that are second-order stochastically dominated (in comparison between lotteries of the same expected value).

- The second definition of riskiness refers to *probability mixtures* [11]. According to this definition, a compound lottery is, *ceteris paribus*, more risky than a simple lottery. More precisely, let us define as a probability mixture of two simple lotteries $\ell_a = (x_a(s_j), p(s_j))_{j=1}^m$ and $\ell_b = (x_b(s_j), p(s_j))_{j=1}^m$, where $S = \{s_1, \dots, s_m\}$ is the set of the states of the nature, the two-stages lottery $\lambda \ell_a \oplus (1-\lambda) \ell_b = (((x_a(s_j), \lambda), (x_b(s_j), (1-\lambda))), p(s_j))_{j=1}^m$, where $\lambda \in [0, 1]$. Figure 5 represents the simplest case of a probability mixture.

Definition 9 (*Aversion to Probability Mixture Increases in Risk*). *An agent is averse to the increases in risk if $CE(\lambda \ell_a \oplus (1-\lambda) \ell_b) \leq \max\{CE(\ell_a), CE(\ell_b)\}$ for every pair of lotteries $\ell_a, \ell_b \in \mathcal{L}$ and $\lambda \in [0, 1]$.*

Note that the expected utility model implies neutrality toward probability mixture increases in risk, since this model satisfies the compound lottery principle, according to which $EU(\lambda \ell_a \oplus (1-\lambda) \ell_b) = \lambda EU(\ell_a) + (1-\lambda) EU(\ell_b)$.

Risk Aversion and Aversion to Increasing Risk with Regard to Rank-dependent Expected Utility

Let us take into consideration a generalization of expected utility theory in order to show some aspects of risk aversion and aversion to increasing risk, which appear very different from the case of expected utility.

Definition 10 (*Rank-dependent Expected Utility* [8, 4]). *The system of preferences $\langle \mathcal{L}, \succsim \rangle$ is represented by rank-dependent expected utility $U : \mathcal{L} \rightarrow \mathbb{R}$ if, for every lottery $\ell \in \mathcal{L}$ with $\ell = (x_i, p_i)_{i=1}^n$ and $x_i > x_{i+1}$ for every $i = 1, \dots, n-1$, where $x_i \in X$ with $X = [\underline{x}, \bar{x}] \subset \mathbb{R}$, we have*

$$U(\ell) = u(x_n) + \sum_{i=1}^{n-1} (u(x_i) - u(x_{i+1})) \varphi \left(\sum_{h=1}^i p_h \right) \quad (5)$$

where function $u : X \rightarrow \mathbb{R}$ represents the system of preferences $\langle X, \succsim \rangle$ over the set of outcomes and function $\varphi : [0, 1] \rightarrow [0, 1]$, which is increasing, with $\varphi(0) = 0$ and $\varphi(1) = 1$, distorts the decumulative probability function.

Thus, the rank-dependent expected utility model describes the agent's system of preferences by means of a utility function on outcomes and a probability distortion function (while the expected utility model requires only the first function). Note that, when

the probability distortion function is the identity function, that is, when $\varphi(p) = p$ for every $p \in [0, 1]$, then rank-dependent expected utility coincides with expected utility.

Recalling that an agent is risk averse if $CE(\ell) \leq EV(\ell)$ for every $\ell \in \mathcal{L}$, that is, if the risk premium $RP(\ell) = EV(\ell) - CE(\ell)$ is nonnegative for every $\ell \in \mathcal{L}$, let us split the risk premium $RP(\ell)$ into two parts: first-order risk premium $RP_1(\ell) = CE_{EU}(\ell) - CE(\ell)$ (with $CE_{EU}(\ell) = u^{-1}(\sum_{i=1}^n p_i u(x_i))$) and second-order risk premium $RP_2(\ell) = EV(\ell) - CE_{EU}(\ell)$.

Proposition 10 [6]. Let $\langle \mathcal{L}, \succsim \rangle$ be represented by rank-dependent expected utility. There is first-order risk aversion, that is, $RP_1(\ell) = CE_{EU}(\ell) - CE(\ell) \geq 0$ for every $\ell \in \mathcal{L}$, if and only if probability distortion function $\varphi : [0, 1] \rightarrow [0, 1]$ is such that $\varphi(p) \leq p$ for every $p \in [0, 1]$. The agent exhibits second-order risk aversion, that is, $RP_2(\ell) = EV(\ell) - CE_{EU}(\ell) \geq 0$ for every $\ell \in \mathcal{L}$, if and only if the utility function $u : X \rightarrow \mathbb{R}$ is concave. As a consequence, an agent is risk averse, that is, $RP(\ell) = EV(\ell) - CE(\ell) \geq 0$ for every $\ell \in \mathcal{L}$, if $\varphi(p) \leq p$ for every $p \in [0, 1]$ and $u : X \rightarrow \mathbb{R}$ is concave. In essence, the condition $\varphi(p) \leq p$ means that the agent overstates the probabilities of some bad outcomes and understates the probabilities of some better outcomes. Because of the probability distortion, rank-dependent expected utility admits first-order risk aversion, therefore allowing for a significant risk aversion even when stakes are small, contrary to expected utility [9]. This may be relevant in finance applications when the agent's choice concerns lotteries in which a small amount of wealth is involved.

Proposition 11 Let $\langle \mathcal{L}, \succsim \rangle$ be represented by rank-dependent expected utility. The agent is locally risk averse if the probability distortion function $\varphi : [0, 1] \rightarrow [0, 1]$ is such that $\varphi(p) < p$ for every $p \in (0, 1)$ and only if $\varphi(p) \leq p$.

In other words, if the rank-dependent expected utility theory holds, then the condition for local risk aversion concerns only the probability distortion function. (As a consequence, the de Finetti–Arrow–Pratt coefficient of risk aversion, which has as its object the utility function $u(\cdot)$, is of no importance in the case of rank-dependent expected utility.)

Another interesting point is that the first-order derivative of risk premium $RP(x + t\ell)$ with

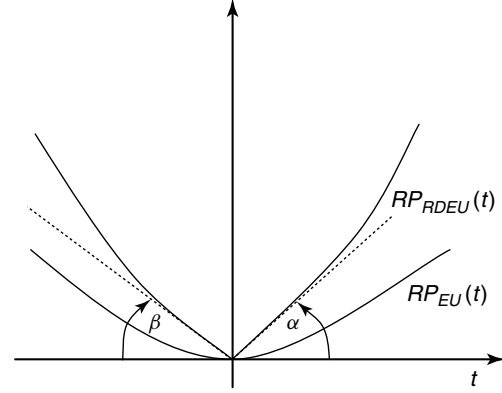

Figure 6 Risk premium function of a risk averse agent

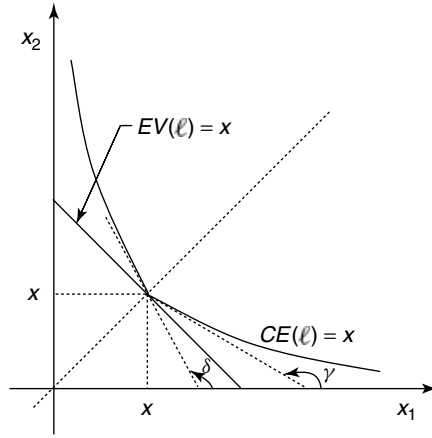

Figure 7 Indifference curve of a risk averse rank-dependent expected utility agent

respect to t is generally nonzero and discontinuous at $t = 0$. For example, if $n = 2$ and $x_1 > x_2$, we get $\lim_{t \rightarrow 0^+} \frac{\partial RP(x + t\ell)}{\partial t} = (x_1 - x_2)(p_1 - \varphi(p_1))$ and $\lim_{t \rightarrow 0^-} \frac{\partial RP(x + t\ell)}{\partial t} = (x_1 - x_2)(p_2 - \varphi(p_2))$. (However, the expected utility theory would yield $\lim_{t \rightarrow 0} \frac{\partial RP(x + t\ell)}{\partial t} = 0$.) In Figure 6, the curve $RP(t)$ represents function $RP(x + t\ell)$ of a risk averse agent, where $\tan \alpha = (x_1 - x_2)(p_1 - \varphi(p_1))$ and $\tan \beta = (x_1 - x_2)(p_2 - \varphi(p_2))$. The curve $RP_{EU}(t)$ represents the same function when the expected utility theory holds. In the Hirshleifer–Yaari diagram (Figure 7), the indifference curves have a kink at $x_1 = x_2$, with $\lim_{x_1 - x_2 \rightarrow 0^+} \frac{dx_2(x_1)}{dx_1} =$

$$\frac{\varphi(p_1)}{1 - \varphi(p_1)} = \tan \gamma \quad \text{and} \quad \lim_{x_1 - x_2 \rightarrow 0^-} \frac{dx_2(x_1)}{dx_1} = \frac{\varphi(p_2)}{1 - \varphi(p_2)} = \tan \delta.$$

If the expected utility theory is valid, then both risk aversion and aversion toward increases in risk (introduced with mean preserving spreads) come from the same condition, which is concavity of the von Neumann–Morgenstern utility function (Propositions 3 and 8). These conditions are different when the rank-dependent expected utility theory holds. Moreover, a rank-dependent expected utility agent may exhibit aversion to probability mixture increases in risk, while the expected utility agent is always neutral.

Proposition 12 *Let $\langle \mathcal{L}, \succsim \rangle$ be represented by rank-dependent expected utility. Then, an agent is averse toward (mean preserving spreads) increases in risk if the function $\varphi : [0, 1] \rightarrow [0, 1]$ is convex and the function $u : X \rightarrow \mathbb{R}$ is concave. He/she is averse toward (probability mixtures) increases in risk if and only if the function $\varphi : [0, 1] \rightarrow [0, 1]$ is convex.*

Ambiguity

In the literature on decision making under uncertainty, *ambiguity* is now consistently used to define those decision settings in which an economic agent perceives “[...] uncertainty about probability, created by missing information that is relevant and could be known” [17]. Other terms have been used interchangeably, notably “Knightian uncertainty,” based on Knight’s [32] distinction between “risk” (a context in which all the relevant “odds” are known and unanimously agreed upon) and “uncertainty” (a context in which some “odds” are not known). The term *ambiguity*, which avoids charging uncertainty with too many meanings, was introduced in [12], the paper that first showed how ambiguity represents a normative criticism to Savage’s [38] subjective expected utility (SEU) model.

Ellsberg proposed two famous thought experiments involving choices on urns in which the exact distribution of ball colors is unknown (one of which was anticipated in both [29] and [32]). A variant of Ellsberg’s so-called two-urn paradox is the following example, due to David Schmeidler. “Suppose that I ask you to make bets on two coins, one taken out of your pocket—a coin, which you have flipped countless times—the other taken out of my pocket. If asked to bet on ‘heads’ or on ‘tails’ on one of the two coins, would you rather bet on your coin or mine?” Most people, when posed this question, announce a mild but strict preference for betting on their own coin rather than on somebody else’s, *both for heads and for tails*. The rationale is precisely that their coin has a well-understood stochastic behavior, while the other person’s coin does not; that is, its behavior is *ambiguous*. The possibility that the coin be biased, although remote, cannot be dismissed altogether. This pattern of preference is called *ambiguity aversion*, and is, as suggested, very common ([6, p. 646] e.g., references many experimental replications of the “paradox”). It is easy to see that it is not compatible with the SEU model. For, suppose that a decision maker has a probabilistic prior P over the state space $S = \{HH, HT, TH, TT\}$ (where HT is the state in which the familiar coin lands heads up and the unfamiliar coin lands tails up, etc.). Then, by saying that he/she prefers a bet that pays off €1 if the familiar coin lands heads up—that is, a bet on the event $A = \{HH, HT\}$ —to the bet that pays €1 if

the unfamiliar coin lands heads up—that is, a bet on the event $B = \{HH, TH\}$ —an SEU decision maker reveals that

$$u(1) P(A) + u(0) (1 - P(A)) > u(1) P(B) + u(0) (1 - P(B)) \quad (1)$$

that is, $P(A) > P(B)$. Analogously, by preferring the bet on tails on the familiar coin to the bet on tails on the unfamiliar coin, an SEU decision maker reveals that

$$P(\{TH, TT\}) = P(A^c) = 1 - P(A) > 1 - P(B) = P(B^c) = P(\{HT, TT\}) \quad (2)$$

that is, $P(A) < P(B)$: a contradiction. Yet, few people would immediately describe these preferences as being an example of irrationality. Ellsberg reports that Savage himself chose in the manner described above, and did not feel that his choices were clearly wrong [12, p. 656]. (Indeed, Savage was aware of the issue well before Ellsberg proposed his thought experiments, for Savage wrote in the *Foundations of Statistics* (pp. 57–58) that “there seem to be some probability relations about which we feel relatively ‘sure’ as compared to others,” adding that he did not know how to make such notion of comparatively “sure” less vague.)

Ellsberg’s paper generated quite a bit of debate immediately after its publication (most of which is discussed in Ellsberg’s PhD dissertation [13]), but the lack of axiomatically founded models that could encompass a concern for ambiguity while retaining most of the compelling features of the SEU model worked to douse the flames. Moreover, the so-called *Allais paradox* [2], another descriptive failure of expected utility, which predated Ellsberg’s by a few years, monopolized the attention of decision theorists until the early 1980s. However, statisticians such as Good [23] and Arthur Dempster [9] did lay the foundations of statistics with sets of probabilities, providing analysis and technical results, which eventually made it into the toolbox of decision theorists.

Models of Ambiguity-sensitive Preferences

The interest in ambiguity as a reason for departure from the SEU model was revived by David Schmeidler, who proposed and characterized axiomatically

two of the most successful models of decision making in the presence of ambiguity, the *Choquet expected utility* (CEU) and the *maxmin expected utility* (MEU) models.

CEU [39] “resolves” the Ellsberg paradox by allowing a decision maker’s willingness to bet on an event to be represented by a set-function that is not necessarily additive; that is, a v , which, to disjoint events A and B , may assign $v(A \cup B) \neq v(A) + v(B)$. More precisely, call a *capacity* any function v defined on a σ -algebra Σ of subsets of a state space S , which satisfies the following properties: (i) $v(\emptyset) = 0$, (ii) $v(S) = 1$, (iii) for any $A, B \in \Sigma$ such that $A \subseteq B$, $v(A) \leq v(B)$. (Note that a *probability (charge)* is v , which satisfies instead of (iii) the property $v(A \cup B) = v(A) + v(B) - v(A \cap B)$ for any $A, B \in \Sigma$.) It is simple to see that if v represents a decision maker’s beliefs, we may observe the preferences described above in the two-coin example. Just substitute P in equations (1) and (2) with v satisfying $v(A) = v(A^c) = 1/2$ and $v(B) = v(B^c) = 1/4$. The obvious question is that of defining expectations for a notion of “belief”, which is not a measure. As the model’s name suggests, Schmeidler used the notion of integral for capacities, which was developed by Choquet [8]. Formally, given a capacity space (S, Σ, v) and a Σ -measurable function $a : S \rightarrow \mathbb{R}$, the *Choquet integral of a with reference to (w.r.t.) v* is given by the following formula:

$$\int_S a(s) dv(s) \equiv \int_0^\infty v(\{s \in S : a(s) \geq \alpha\}) d\alpha + \int_{-\infty}^0 [v(\{s \in S : a(s) \geq \alpha\}) - 1] d\alpha \quad (3)$$

This is shown to correspond to Lebesgue integration when the capacity v is a probability. Schmeidler provided axioms on a decision maker’s preference relation $\succsim$, which guarantee that the latter is represented by the Choquet expectation w.r.t. v of a real-valued utility function u (on final prizes $x \in X$). Precisely, given choice options (acts) $f, g : S \rightarrow X$,

$$f \succsim g \iff \int_S u(f(s)) dv(s) \geq \int_S u(g(s)) dv(s) \quad (4)$$

That is, the decision maker prefers f to g whenever the Choquet integral of $u \circ f$ is greater than that

of $u \circ g$. The interested reader is referred to Schmeidler’s paper for details of the axiomatization. For our purpose, it suffices to observe that, not too surprisingly, the key axiomatic departure from SEU (in the variant due to [3]) is a relaxation of the independence axiom—or what Savage calls the *sure-thing principle*—which is the property of preferences that the Ellsberg-like preferences above violate.

Not all capacities give rise to behavior which is averse to ambiguity, as in the above example. Schmeidler proposed the following behavioral notion of aversion to ambiguity. Assuming that the payoffs x can themselves be (objective and additive) lotteries over a set of certain prizes, define for any $\alpha \in [0, 1]$ the α -mixture of acts f and g as follows: for any $s \in S$,

$$(\alpha f + (1 - \alpha)g)(s) \equiv \alpha f(s) + (1 - \alpha)g(s) \quad (5)$$

where the object on the right-hand side is the lottery that pays off prize $f(s)$ with probability α and prize $g(s)$ with probability $(1 - \alpha)$. Now, say that a preference satisfies *ambiguity hedging* (Schmeidler calls this property *uncertainty aversion*) if for any f and g such that $f \sim g$ we have

$$\alpha f + (1 - \alpha)g \succsim f \quad (6)$$

for any α . That is, the decision maker *may* prefer to “hedge” the ambiguous returns of two indifferent acts by mixing them appropriately. This makes sense if we consider two acts whose payoff profiles are negatively correlated (over S), so that the mixture has a payoff profile, which is flatter, hence less sensitive to the information on S , than the original acts. (Ghirardato and Marinacci [20] discuss ambiguity hedging, arguing that it captures more than just the ambiguity aversion of equations 1 and 2.) Schmeidler shows that a CEU decision maker satisfies ambiguity hedging if and only if her capacity v is *supermodular*; that is, for any $A, B \in \Sigma$,

$$v(A \cup B) \geq v(A) + v(B) - v(A \cap B) \quad (7)$$

Ambiguity hedging also plays a key role in the second model of ambiguity-sensitive preferences proposed by Schmeidler, the MEU model introduced alongside that of Itzhak Gilboa [21]. In MEU, the decision maker’s preferences are represented by (a utility function u and) a *set* C of probability charges

on (S, Σ) —which is nonempty, (weak*)-closed and convex—as follows:

$$\begin{aligned} f \succsim g &\iff \min_{P \in C} \int_S u(f(s)) dP(s) \\ &\geq \min_{P \in C} \int_S u(g(s)) dP(s) \end{aligned} \quad (8)$$

Thus, the presence of ambiguity is reflected by the nonuniqueness of the prior probabilities over the set of states. In the authors’ words, “the subject has too little information to form a prior. Hence, (s)he considers a *set* of priors as possible” [21, p. 142]. In the two-coin example, let S be the product space $\{H, T\} \times \{H, T\}$ and consider the set of priors

$$C \equiv \cup_{a \in [1/4, 3/4]} \{1/2, 1/2\} \times \{a, 1-a\} \quad (9)$$

It is easy to see that a decision maker with such a C will “assign” to events A and A^c the weight $\min_{P \in C} P(A) = 1/2 = \min_{P \in C} P(A^c)$, and to events B and B^c the weight $\min_{P \in C} P(B) = 1/4 = \min_{P \in C} P(B^c)$, thus displaying the classical Ellsberg preferences. Gilboa and Schmeidler showed that MEU is axiomatically very close to CEU. While ambiguity hedging is required (being single-handedly responsible for the “min” in the representation; see [19]), a weaker version of independence is used.

Ambiguity hedging characterizes the intersection of the CEU and MEU models. Schmeidler [39] shows that a decision maker’s preferences have *both* CEU and MEU representations if and only if (i) the v in the CEU representation is supermodular, and (ii) the lower envelope of the set C in the MEU representation, $\underline{C}(\cdot) \equiv \min_{P \in C} P(\cdot)$, is a supermodular capacity and C is the set of *all* the probability charges that dominate $\underline{C}$ (the *core* of $\underline{C}$). On the other hand, there are CEU preferences that are not MEU (take a capacity v which is not supermodular), and MEU preferences that are not CEU (see [30, Example 1]).

The CEU and MEU models brought ambiguity back to the forefront of decision theoretic research, and in due course, as “applications” of such theoretical models started to appear, they were key in attracting the attention of mainstream economics and finance.

On the theoretical front, a number of alternative axiomatic models have been developed. First, there are generalizations of CEU and MEU. For instance, Maccheroni *et al.* [33] presented a model that they

called *variational preferences*, which relaxes the independence condition used in MEU while retaining the ambiguity hedging condition. An important special case of variational preferences is the so-called *multiplier model* of Hansen and Sargent [25], a key model in the applications literature to be discussed later. Siniscalchi [42] proposed a model that he called *vector expected utility*, in which an act is evaluated by modifying its expectation (w.r.t. a “baseline probability”) by an adjustment function capturing ambiguity attitudes. Such a model is also built with applications in mind, as it (potentially) employs a smaller number of parameters than CEU and MEU.

Second, Bewley [4] (originally circulated in 1986) suggested that ambiguity might result in incompleteness of preferences, rather than in violation of independence. Under such assumptions, he found a representation in which a set of priors C appears in a “unanimity” sense as follows:

$$\begin{aligned} f \succsim g &\iff \int_S u(f(s)) dP(s) \\ &\geq \int_S u(g(s)) dP(s) \text{ for all } P \in C \end{aligned} \quad (10)$$

That is, the decision maker prefers f over g whenever f dominates g according to every “possible scenario” in C . Preferences are undecided otherwise, and Bewley suggested completing them by following an “inertia” rule: the *status quo* is retained if undominated by any available act. In a model that joins the two research strands just described, Ghirardato *et al.* [19] showed that if we drop ambiguity hedging from the MEU axioms, we can still obtain the set of priors C as a “unanimous” representation of a suitably defined incomplete subset of the decision maker’s preference relation, which they interpreted as “unambiguous” preference (i.e., a preference that is not affected by the presence of ambiguity). This yields a model—of which both CEU and MEU are special cases—in which the decision maker evaluates act f *via* the functional

$$\begin{aligned} V(f) &= a(f) \min_{P \in C} \int_S u(f(s)) dP(s) \\ &\quad + (1 - a(f)) \max_{P \in C} \int_S u(f(s)) dP(s) \end{aligned} \quad (11)$$

where $a(f) \in [0, 1]$ is the decision maker's ambiguity aversion in evaluating f (a generalization of the decision rule suggested by Hurwicz [27]).

A third modeling approach relaxes the “reduction of compound lotteries” property that is built within the expected utility model. The basic idea is that the decision maker forms a “second-order” probability μ over the set of possible priors over S , and that he/she does not reduce the resulting compound probability. That is, he/she could evaluate act f by first calculating its expectation $E_P(u \circ f) \equiv \int u(f(s)) dP(s)$ with respect to each prior P that he/she deems possible, and then computing

$$\int_{\Delta} \phi(E_P(u \circ f)) d\mu(P) \quad (12)$$

where Δ denotes the set of all possible probability charges on (S, Σ) , and $\phi : \mathbb{R} \rightarrow \mathbb{R}$ is a function, which is not necessarily affine. This is the reasoning adopted by Segal [40], followed by Ergin and Gul [16], Klibanoff *et al.* [31], Nau [37], and Seo [41]. The case of SEU corresponds to ϕ being affine, while Klibanoff *et al.* [31] show that ϕ being concave corresponds intuitively to ambiguity averse preferences. That is, the “external” utility function describes ambiguity attitude, while the “internal” one describes risk attitude. An important feature of such a model is that its representation is smooth (in utility space), whereas those of MEU and CEU are generally not. For this reason, this is called the *smooth ambiguity model*.

In concluding this brief survey of decision models, it is important to stress that, owing to space constraint, the focus is on *static* models. The literature on *intertemporal* models is more recent and less developed, in part, because of the fact that non-SEU preferences often violate a property called *dynamic consistency* [18], making it hard to use the traditional dynamic programming tools. Important contributions in this area are found in [14, 22] (characterizing the so-called *recursive MEU* model) and [24, 34].

Applications

As mentioned above, the CEU and MEU models were finally successful in introducing ambiguity into mainstream research in economics and finance. Many papers have been written, which assume that (some) agents have CEU or MEU preferences. The interested reader is referred to [36] for an extensive survey of

such applications, while some applications to finance are briefly discussed here.

In a seminal contribution, Dow and Werlang [10] showed that a CEU agent with supermodular capacity may display a nontrivial bid–ask spread on the price of an (ambiguous) Arrow security, even without frictions. If the price of the security falls within such an interval, the agent will not want to trade the security at all (given an initial riskless position). Epstein and Wang [15] employed the recursive MEU model to study the equilibrium of a representative agent economy *à la Lucas*. They showed that price indeterminacy can arise in equilibrium for reasons that are closely related to Dow and Werlang's observation. Other contributions followed along this line; for example, see [7, 35, 43]. More recently, the smooth ambiguity model has also been receiving attention; see, for example, [28].

Though originally not motivated by the Ellsberg paradox and ambiguity, the “model uncertainty” literature due to Hansen *et al.* ([26], but more comprehensively found in [25]) falls squarely within the scope of the applications of ambiguity. Moreover, both decision models they employ are special cases of the models described above: the “multiplier model” is a special case of variational preferences, and the “constraint model” is a special case of MEU.

Most of the applications of ambiguity to finance—an exception being [11]—are cast in a representative agent environment, with the preferences of the representative agent satisfying in one case MEU, in another CEU, and so on. Recent work on experimental finance by Bossaerts *et al.* [5] and Ahn *et al.* [1] finds that experimental subjects, when making portfolio choices with ambiguous Arrow securities, display substantial heterogeneity in ambiguity attitudes. Because Bossaerts *et al.* [5] show that such heterogeneity may easily result in a breakdown of the representative agent result, such findings cast some doubt on the generality of a representative agent approach to financial markets equilibrium.

Risk Premia

Risk premia are the expected excess returns that compensate investors for taking on aggregate risk. The first section of this article defines risk premia analytically. The second section surveys empirical evidence on equity, bond, and currency excess returns. The third section reviews the models that explain these risk premia.

Theoretical Definition

Risk premia are derived analytically from Euler equations that link returns to stochastic discount factors (SDFs). These Euler equations can be derived under three different assumptions: complete markets, the law of one price, or the existence of investors' preferences. These three assumptions are reviewed here, followed by the analytical definition of risk premia.

Euler Equations

Utility-based Asset Pricing. Assume that the investor derives some utility u from consumption C now and in the next period. This setup can be easily generalized to many periods. Let us find the price P_t at time t of a payoff X_{t+1} at time $t + 1$. Let Q be the original consumption level in the absence of any asset purchase and let ξ be the amount of the asset the investor chooses to buy. The constant subjective discount factor is β . The maximization problem of this investor is

$$\begin{aligned} & \text{Max}_{\xi} \quad u(C_t) + E_t[\beta u(C_{t+1})] \\ & \text{subject to: } C_t = Q_t - P_t \xi, \\ & \quad C_{t+1} = Q_{t+1} + X_{t+1} \xi \end{aligned} \quad (1)$$

Substituting the constraints into the objective and setting the derivative with respect to ξ to zero yields

$$P_t u'(C_t) = E_t[\beta u'(C_{t+1}) X_{t+1}] \quad (2)$$

where $P_t u'(C_t)$ is the loss in utility if the investor buys another unit of the asset, and $E_t[\beta u'(C_{t+1}) X_{t+1}]$ is the expected and discounted increase in utility he/she obtains from the extra payoff X_{t+1} . The

investor continues to buy or sell the asset until the marginal loss equals the marginal gain. The Euler equation is thus

$$P_t = E_t \left[\beta \frac{u'(C_{t+1})}{u'(C_t)} X_{t+1} \right] = E_t[M_{t+1} X_{t+1}] \quad (3)$$

where the SDF M_{t+1} is defined as $M_{t+1} \equiv \beta u'(C_{t+1})/u'(C_t)$.

Complete Markets. Let us now abstract from utilities and assume that markets are *complete*. There are S states of nature tomorrow, and s denotes an individual state. A contingent claim is a security that pays one dollar (or one unit of the consumption good) in one state s only tomorrow. The price today of this contingent claim is $P_c(s)$. In complete markets, investors can buy any contingent claim (or synthesize all contingent claims). Let $\underline{X}$ be the payoff space and $X(s) \in \underline{X}$ denote an asset's payoff in state of nature s . Let $\pi(s)$ be the probability that state s occurs. Then the price of this asset is

$$P(X) = \sum_{s=1}^S P_c(s) X(s) = \sum_{s=1}^S \pi(s) \frac{P_c(s)}{\pi(s)} X(s) \quad (4)$$

We define M as the ratio of the contingent claim's price to the corresponding state's probability $M(s) \equiv P_c(s)/\pi(s)$ to obtain the Euler equation in complete markets:

$$P(X) = \sum_{s=1}^S \pi(s) M(s) X(s) = E(MX) \quad (5)$$

Law of One Price and the Absence of Arbitrage.

Finally, assume now that markets are *incomplete* and that we simply observe a set of prices P and payoffs X . Under a minimal set of assumptions, some discount factor exists that represents the observed prices by the same equation $P = E(MX)$. These assumptions are defined below:

Definition 1 *Free portfolio formation:* $X_1, X_2 \in \underline{X} \Rightarrow aX_1 + bX_2 \in \underline{X}$ for any real a and b .

Definition 2 *Law of one price:* $P(aX_1 + bX_2) = aP(X_1) + bP(X_2)$.

Note that free portfolio formation rules out short sales constraints, bid/ask spreads, leverage limitations, and so on. The law of one price says

that investors cannot make instantaneous profits by repackaging portfolios. These assumptions lead to the following theorem:

Theorem 1 *Given free portfolio formation and the law of one price, there exists a unique payoff $X^* \in \underline{X}$ such that $P(X) = E(X^*X)$ for all $X \in \underline{X}$.*

As a result, there exists an SDF M such that $P(X) = E(MX)$. Note that the existence of a discount factor implies the law of one price $E[M(X + Y)] = E[MX] + E[MY]$. The theorem reverses this logic. Cochrane [7] offers a geometric and an arithmetic proof. With a stronger assumption, the absence of arbitrage, the SDF is strictly positive and thus represents some—potentially unknown—preferences. Let us first review the definition of the absence of arbitrage and then turn to this new theorem.

Definition 3 *Absence of arbitrage: A payoff space $\underline{X}$ and pricing function $P(X)$ leave no arbitrage opportunities if every payoff X that is always nonnegative ($X \geq 0$ almost surely) and strictly positive ($X > 0$) with some positive probability has some strictly positive price $P(X) > 0$.*

In other words, no arbitrage says that one cannot get for free a portfolio that might pay off positively but will certainly never cost one anything. This assumption leads to the next theorem:

Theorem 2 *No arbitrage and the law of one price imply the existence of a strictly positive discount factor $M > 0$ such that $P = E(MX)$, $\forall X \in \underline{X}$.*

We have seen three ways to derive the Euler equation that links any asset's price to the SDF. Before we exploit the Euler equation to define risk premia, note that only aggregate risk matters for asset prices.

Aggregate and Idiosyncratic Risk. Only the component of payoffs that is correlated with the SDF shows up in the asset's price. Idiosyncratic risk, uncorrelated with the SDF, generates no premium. To see this, let us project X on M and decompose the payoff as follows:

$$X = \text{proj}(X|M) + \varepsilon \quad (6)$$

Projecting X on M is like regressing X on M without a constant:

$$\text{proj}(X|M) = \frac{E(MX)}{E(M^2)}M \quad (7)$$

The residuals ε are orthogonal to the right-hand side variable M : $E(M\varepsilon) = 0$, which means that the price of ε is zero. The price of the projection of X on M is the price of X :

$$P(\text{proj}(X|M)) = E\left(M \frac{E(MX)}{E(M^2)}M\right) = E(MX) \quad (8)$$

Payoffs and Returns. We have reviewed three frameworks that lead to the Euler equation. This equation defines the asset price P for any asset. For stocks, the payoff X_{t+1} is the price next period P_{t+1} and the dividend D_{t+1} . For a one-period bond, the payoff is 1: one buys a bond at price P_t and receive 1 dollar next period. Alternatively, we can write the Euler equation in terms of returns. For stocks, returns are payoffs divided by prices: $R_{t+1} = X_{t+1}/P_{t+1}$. For bonds, one pays 1 dollar today and receives R_{t+1} dollars tomorrow. In any case, the Euler equation in terms of returns is thus

$$E_t[M_{t+1}R_{t+1}] = 1 \quad (9)$$

The Euler equation naturally applies to a risk-free asset. If one pays 1 dollar today and receives R_t^f dollars tomorrow for sure, the risk-free rate R_t^f satisfies

$$R_t^f = 1/E_t[M_{t+1}] \quad (10)$$

Expected Excess Returns

Definition of Risk Premia. Applying the definition of the covariance to the Euler equation (9) for the asset return R^i leads to $E_t(M_{t+1})E_t(R_{t+1}^i) + \text{cov}_t[M_{t+1}, R_{t+1}^i] = 1$. Using the definition of the risk-free rate in equation (10), we obtain

$$E_t(R_{t+1}^i) - R_t^f = -R_t^f \text{cov}_t[M_{t+1}, R_{t+1}^i] \quad (11)$$

The left-hand side of equation (11) defines the expected excess return. The right-hand side of equation (11) defines the risk premium. When the asset return R^i is negatively correlated to the SDF, the investor expects a positive excess return on asset

i. All assets have an expected return equal to the risk-free rate, plus a risk adjustment that is positive or negative.

To gain some intuition on the definition above, let us consider the case of preference-based SDFs. Assume that utility increases, and marginal utility decreases with consumption; this is the consumption-capital asset pricing model (consumption-CAPM). Here, the SDF—also known as *intertemporal marginal rate of substitution*—is the ratio of marginal utility of consumption tomorrow divided by the marginal utility of consumption today. Substituting the SDF into equation (11), we obtain

$$E_t(R_{t+1}^i) - R_t^f = -R_t^f \frac{\text{Cov}_t[\beta u'(C_{t+1}), R_{t+1}^i]}{u'(C_t)} \quad (12)$$

Marginal utility $u'(C)$ declines as consumption C rises. Thus, an asset's expected excess return is positive if its return covaries positively with consumption. The reason for this can be explained as follows. Our assumption on the investors' utility function implies that investors dislike uncertainty about consumption. An asset whose return covaries positively with consumption pays off well when the investor is already feeling wealthy and it pays off badly when he/she is already feeling poor. Thus, such an asset will make the investor's consumption stream more volatile. As a result, assets whose returns covary positively with consumption make consumption more volatile, and so must promise higher expected returns to induce investors to hold them.

Beta-representation and Market Price of Risk. We can rewrite the right-hand side of equation (11) as

$$\underbrace{\left(-\frac{\text{Cov}_t[M_{t+1}, R_{t+1}^i]}{\text{Var}_t[M_{t+1}]} \right)}_{\beta_{i,M}} \underbrace{\left(\frac{\text{Var}_t[M_{t+1}]}{E_t[M_{t+1}]} \right)}_{\lambda_M} \quad (13)$$

$E(R_{t+1}^i) - R_t^f = \beta_{i,M} \lambda_M$ is then a beta-representation of the Euler equation. Note that λ_M is independent of the asset i . It is called the *market price of risk*. $\beta_{i,M}$ is the quantity of risk. The expected excess return on asset i is equal to the quantity of risk of this asset times the price of risk.

Euler Equation with Log Returns and Log SDF. To interpret risk premia, it is often easier to rewrite

the previous results in terms of the log SDF m_{t+1} and log return r_{t+1}^i . Assuming that SDF and returns are lognormal, equation (9) leads to

$$E_t(m_{t+1}) + E_t(r_{t+1}^i) + \frac{1}{2} \text{Var}_t(m_{t+1}) + \frac{1}{2} \text{Var}_t(r_{t+1}^i) + \text{Cov}_t(m_{t+1}, r_{t+1}^i) = 0 \quad (14)$$

where lowercase letters denote logs. The same equation holds for the risk-free rate r_t^f . Let $\tilde{r}_{t+1}^{e,i}$ be the excess return corrected for the Jensen term: $\tilde{r}_{t+1}^{e,i} = r_{t+1}^i - r_t^f + \frac{1}{2} \text{Var}_t(r_{t+1}^i)$. Then, the expected log excess return is equal to

$$E_t(\tilde{r}_{t+1}^{e,i}) = -\text{Cov}_t(m_{t+1}, \tilde{r}_{t+1}^{e,i}) \quad (15)$$

For the consumption-CAPM, the utility each period is $u(C) = C^{1-\gamma}/(1-\gamma)$. The log SDF depends only on consumption growth and is equal to $m_{t+1} = \log \beta - \gamma g - \gamma(\Delta c_{t+1} - g)$, where g is the average consumption growth. In this case, the expected excess return is equal to

$$E_t(\tilde{r}_{t+1}^{e,i}) = \gamma \text{Cov}_t(\Delta c_{t+1} - g, \tilde{r}_{t+1}^{e,i}) \quad (16)$$

Again, assets whose returns covary positively with consumption must promise positive expected returns to induce investors to hold them.

Empirical Evidence

Now the empirical stylized facts on risk premia are discussed. A large literature shows that, in many asset markets, expected excess returns are sizable and time-varying. The equity, bond, and currency markets are considered (*see Predictability of Asset Prices*).

Stock Markets

Evidence of large risk premia abound on equity markets. The size of the average excess return on the stock market is actually puzzling from a consumption-based asset pricing perspective; it constitutes the equity premium puzzle. Moreover, expected equity returns appear time-varying.

Equity Premium Puzzle. To understand the equity premium puzzle, let us first define the Sharpe ratio.

Definition 4 The Sharpe ratio SR measures how much return the investor receives per unit of volatility:

$$SR = \frac{E(R^i) - R^f}{\sigma(R^i)} \quad (17)$$

where $\sigma(R^i)$ denotes the standard deviation of the return R^i .

Over the period 1927–2006 in the United States, real excess returns on the New York Stock Exchange (NYSE) stock index have averaged 8%, with a standard deviation of 20%, and thus the Sharpe ratio has been about 0.4. Starting from equation (11) and using the fact that correlations are below unity, the Sharpe ratio is linked to the first and second moments of SDFs:

$$\left| \frac{E(R^i) - R^f}{\sigma(R^i)} \right| \leq \left| \frac{\sigma(M)}{E(M)} \right| \quad (18)$$

Now, recall the consumption-CAPM and assume that consumption is lognormal. Then, the right-hand side is approximately

$$\frac{\sigma(M)}{E(M)} = \sqrt{e^{\gamma^2 \sigma_{\Delta c}^2} - 1} \approx \gamma \sigma_{\Delta c} \quad (19)$$

Aggregate nondurable and services consumption growth has a mean of 2% and a standard deviation of 1%, implying a risk-aversion coefficient of 40! If we take into account the low correlation between consumption growth rates and market returns, the implied risk aversion is even higher. This is the equity premium puzzle of Mehra and Prescott [16]. Such a high risk-aversion coefficient implies implausibly high risk-free rates. This is the risk-free rate puzzle of Weil [19]. The above-mentioned evidence is based on *realized* excess returns. Yet similar results are obtained with *expected* excess returns, which turn out to be large and time-varying.

Time-varying Expected Excess Returns. The Campbell and Shiller [5] decomposition of stock returns frames the evidence on stock market predictability. To see this, start from $1 = R_{t+1}^{-1} R_{t+1} = R_{t+1}^{-1} (P_{t+1} + D_{t+1}) / P_t$, and multiply both sides by the price-dividend ratio P_t / D_t to obtain

$$\frac{P_t}{D_t} = R_{t+1}^{-1} \left(1 + \frac{P_{t+1}}{D_{t+1}} \right) \frac{D_{t+1}}{D_t} \quad (20)$$

Taking logs leads to

$$p_t - d_t = -r_{t+1} + \Delta d_{t+1} + \log(1 + e^{p_{t+1} - d_{t+1}}) \quad (21)$$

A first-order Taylor approximation of the last term around the mean price-dividend ratio P/D gives

$$p_t - d_t = -r_{t+1} + \Delta d_{t+1} + k + \rho(p_{t+1} - d_{t+1}) \quad (22)$$

where $k = \log(1 + P/D)$ and $\rho = (P/D)/(1 + P/D)$. Iterating forward and assuming that $\lim_{j \rightarrow \infty} \rho^j(p_{t+j} - d_{t+j}) = 0$, one obtains

$$p_t - d_t = \text{Constant} + \sum_{j=1}^{\infty} \rho^{j-1} (\Delta d_{t+j} - r_{t+j}) \quad (23)$$

This equation holds *ex-post*, and thus also *ex-ante*:

$$p_t - d_t = \text{Constant} + E_t \sum_{j=1}^{\infty} \rho^{j-1} (\Delta d_{t+j} - r_{t+j}) \quad (24)$$

Now multiply both sides by $p_t - d_t - E(p_t - d_t)$. Then the variance of the log price-dividend ratio is

$$\begin{aligned} & \text{cov} \left(p_t - d_t, \sum_{j=1}^{\infty} \rho^{j-1} \Delta d_{t+j} \right) \\ & - \text{cov} \left(p_t - d_t, \sum_{j=1}^{\infty} \rho^{j-1} r_{t+j} \right) \end{aligned} \quad (25)$$

The fact that the price-dividend ratio varies means that either dividend growth rates or returns must be forecastable. The question is: which one is forecastable? Long-horizon regressions show little predictability in dividend growth rates and some predictability in returns and excess returns (Table 1).

We have seen that the aggregate stock market offers evidence of sizable and time-varying risk premia. Many subsets of the market offer comparable results. For example, Fama and French [12] sort stocks along different dimensions (e.g., their market size, book-to-market ratios, or past returns), build the corresponding portfolios and obtain large cross sections of returns. Buying the stocks in the last portfolio and selling the ones in the first portfolio lead to large and predictable excess returns, and thus evidence of equity risk premia.

Table 1 Long-horizon stock market predictability tests

Horizon h	Excess returns			Dividend growth		
	α	s.e.	R^2	α	s.e.	R^2
1	3.77	1.38	0.07	-0.11	1.00	0.00
2	7.46	2.36	0.12	-0.76	0.86	0.01
3	12.07	3.70	0.18	0.12	0.98	0.00
4	17.62	5.27	0.24	0.41	1.26	0.00
5	22.01	5.66	0.29	0.03	0.89	0.00

This table reports slope coefficients α , standard errors s.e. and R^2 from in-sample predictability tests. In the left panel, the univariate regressions are $R_{t,t+h}^e = C + \alpha D_t/P_t + \varepsilon_{t+h}$, where $R_{t,t+h}^e$ denotes the h -year ahead stock market excess return and D_t/P_t the dividend-price ratio. In the right panel, the regressions are $D_{t+h}/D_t = C + \alpha D_t/P_t + \varepsilon_{t+h}$, where D_{t+h}/D_t denotes the h -year ahead dividend growth rate. The sample relates to the period 1927–2006. Data are annual

Bond Markets

Equivalent results are obtained on bond markets, where expected excess returns exist and are time-varying. These results contradict the usual “expectation hypothesis of the term structure”. It is reviewed, followed by the empirical evidence on bond excess returns (see **Expectations Hypothesis**).

The expectation hypothesis can be defined in three equivalent ways:

- The yield y_t^n of a bond with maturity n is equal to the average of the expected yields of future one-year bonds, up to a constant risk premium:

$$y_t^n = \frac{1}{n} E_t(y_t^1 + y_{t+1}^1 + \cdots + y_{t+n-1}^1) \quad (26)$$

- The forward rate equals the expected future spot rate, up to a constant risk premium:

$$f_t^{n \rightarrow n+1} = E_t(y_{t+n}^1) \quad (27)$$

- The expected holding-period return (defined as the return on buying a bond of a given maturity n and selling it in the next period) is the same for any maturity n , up to a constant risk premium:

$$E_t(hpr_{t+1}^n) = y_t^1, \forall n \quad (28)$$

where $hpr_{t+1}^n = p_{t+1}^{n-1} - p_t^n$ denotes the log holding-period return and p_t^n the log price of a bond of maturity n .^a

Following Campbell and Shiller [6], the expectation hypothesis is often tested with the following

Table 2 Expectation hypothesis tests

$n = 2$	$n = 3$	$n = 4$	$n = 5$
-0.88 [0.47]	-1.46 [0.48]	-1.62 [0.53]	-1.70 [0.61]

This table reports slope coefficients β_n and associated standard errors from the following univariate regressions: $y_{t+1}^{n-1} - y_t^n = \alpha + \beta_n \left(\frac{y_t^n - y_t^1}{n-1} \right) + \varepsilon_{t+1}$, where y_t^n denotes the n -year bond yield. The sample relates to the period 1952–2006. Data are annual

equation:

$$y_{t+1}^{n-1} - y_t^n = \alpha + \beta_n \left(\frac{y_t^n - y_t^1}{n-1} \right) + \varepsilon_{t+1} \quad (29)$$

The expectation hypothesis implies that $\beta_n = 1$. In the data, the slope coefficient β_n is significantly below 1, often negative, and decreasing with the horizon n (Table 2). The rejection of the expectation hypothesis implies that bond markets offer time-varying, expected excess returns.

Currency Markets

Risk premia are also prevalent on currency markets. Currency excess returns correspond to the following investment strategy: borrowing in the domestic currency, exchanging this amount for some foreign currency, lending abroad, and converting back the earnings into the domestic currency. According to the standard uncovered interest rate parity (UIP) condition, the expected change in exchange rate should be equal to the interest rate differential between foreign

and domestic risk-free bonds. In this case, expected currency excess returns should be zero. However, the UIP condition is clearly rejected in the data. In a simple regression of exchange rate changes on interest rate differentials, UIP predicts a slope coefficient of 1. Instead, empirical work following Hansen and Hodrick [13] and Fama [11] consistently reveals a regression coefficient that is smaller than 1 and very often negative. The international economics literature refers to these negative UIP slope coefficients as the UIP puzzle or forward premium anomaly. Negative slope coefficients mean that currencies with higher than average interest rates actually tend to appreciate. Investors in foreign one-period discount bonds thus earn the interest rate spread, which is known at the time of their investment, plus the bonus from the appreciation of the currency during the holding period. As a result, the failure of the UIP condition implies positive predictable excess returns when investing in high interest rate currencies and negative excess returns for investing in low interest rate currencies. Lustig and Verdelhan [15] build portfolios of currency excess returns by sorting currencies on their interest rate differentials with the United States. They obtain a large cross section of currency excess returns and show that these excess returns compensate the US investor for bearing US aggregate macroeconomic risk because high interest rate currencies tend to depreciate in bad times. As a result, currency excess returns are also evidence of risk premia.

To summarize this section, equity, bond, and currency markets offer predictable excess returns, and are thus characterized by risk premia. Now the potential theoretical explanations of these risk premia are discussed.

Theoretical Interpretations

As observed above, the consumption-CAPM (also known as *power utility*) can replicate average equity excess returns only with implausibly high risk-aversion coefficients. Moreover, if consumption growth shocks are close to independent and identically distributed (i.i.d.)—as they are in the data—this model does not explain time variations in expected excess returns. A large literature seeks to address these shortcomings and offers different interpretations of the observed risk premia. Now the three most

successful classes of models in this literature, namely, habit preferences, long-run risk, and disaster risk, are reviewed.

Habit Preferences

Habit preferences assume that the agent does not care about the absolute level of his/her consumption, but cares about its relative level compared to a habit level that can be interpreted as a subsistence level, past consumption, or the neighbors' consumption. Hence, preferences over habits H are defined using ratios or differences (C/H or $C - H$), where H depends on past consumption: $H_t = f(C_{t-1}, C_{t-2}, \dots)$. Major examples of habit preferences are found in Abel [1], Campbell and Cochrane [4], Constantinides [8] and Sundaresan [18]. Preferences defined using differences between consumption and habit (e.g., $u(C) = (C - H)^{-\gamma}$) imply time-varying risk-aversion coefficient if the percentage gap between consumption and habit changes through time:

$$\gamma_t = -\frac{CU_{CC}}{U_C} = \frac{\gamma H_t}{C_t - H_t} \quad (30)$$

Campbell and Cochrane [4] propose a model along these lines. In their model, the habit level is slow moving; in bad times, consumption falls close to the habit level, and the investor is very risk averse. This model offers a new interpretation to risk premia: investors fear bad returns and wealth loss because they tend to happen in recessions, when consumption falls relative to its recent past. These preferences generate many interesting asset pricing features: pro-cyclical variations of stock prices, long-horizon predictability, countercyclical variation of stock market volatility, countercyclicity of the Sharpe ratio, and the short- and long-run equity premium.

Long-run Risk

The long-run risk literature works off the class of preferences due to Epstein and Zin [9, 10] and Kreps and Porteus [14]. These preferences impute a concern for the timing of the resolution of uncertainty to agents, and the risk-aversion coefficient is no longer the inverse of the intertemporal elasticity of substitution as it is with the consumption-CAPM (*see Recursive Preferences*). Building on these preferences,

Bansal and Yaron [2] propose a model where the consumption and dividend growth processes contain a low-frequency component and are heteroscedastic. These two features capture time-varying growth rates and time-varying economic uncertainty. Because this low-frequency component is persistent, a high value today signals high expected consumption growth in the future. If the intertemporal elasticity of substitution is above 1, then, in response to higher expected growth, agents buy more assets, and the price to consumption ratio rises: the intertemporal substitution effect dominates the wealth effect. In this case, asset prices are high in good times and low in bad times; thus, investors require risk premia. In this model, agents have preference for early resolution of uncertainty, which increases the risk compensation for long-run growth and uncertainty risks.

Disaster Risk

In the disaster risk literature, the agent is characterized by the usual constant relative risk-aversion preferences. Rietz [17] assumes that in each period a small-probability disaster may occur, and in this case, consumption and dividends drop sharply. Barro [3] calibrates disaster probabilities from the twentieth-century global history and shows that they are consistent with the high equity premium, low risk-free rate, and volatile stock returns. In this model, risk premia exist because investors fear rare economic disasters.

Conclusion

Under a minimal set of assumptions, any return satisfies a simple Euler equation. This equation implies that expected returns in excess of the risk-free rate, that is, risk premia, exist because returns comove with aggregate factors that matter for the investor. Empirical evidence from the equity, bond, and currency markets points to large and time-varying predictable excess returns. A recent literature tries to replicate and interpret these risk premia as compensations for recession, long-run, or disaster risks.

Acknowledgments

I owe a great part of my knowledge on risk premia to John Cochrane and to his book on “Asset Pricing”, which has inspired large parts of this article.

End Notes

^aRecall that the yield y_t^n of an n -year bond is a fraction of the log price p_t^n of the bond: $y_t^n = -\frac{1}{n}p_t^n$.

Predictability of Asset Prices

Predictability can be interpreted in many ways in finance. The fundamental issue in asset pricing is to determine the relationship between risk and reward. To quantify such a relationship, an economic model is built to “predict” how the expected asset returns should vary with their risk measures. In this case, predictability means contemporaneous association between the expected return of an asset and the expected returns of different risk factors. For example, the capital asset pricing model (CAPM) predicts that a security’s expected risk premium is proportional to the expected return from the market factor, where the proportionality reflects the systematic risk measure. This type of predictability is not the focus of this article. Instead, the focus is on whether future security returns can be predicted from current known information.

One important assumption used to build a rational asset pricing model is the market efficiency (*see Efficient Market Hypothesis*), in which security prices reflect all available information quickly and fairly. This was interpreted literally in the 1950s and 1960s as saying that any lagged variables possess no power in predicting current or future security prices or returns. The modern finance theory, however, has a different interpretation for the evidence of return predictability. In fact, researchers have recognized since 1980s that the expected returns can vary over time due to changes in investors’ risk tolerance and/or investment opportunities [30] over business cycles. If business cycles are predictable to some degree, returns can also be predictable, which poses no challenge to the efficient market hypothesis (EMH). Under this view, one should not rely solely on the historical average returns to estimate expected returns in assisting our investment decisions. In other words, the task of estimating the expected returns precisely largely depends on our ability to predict future stock returns.

Given the fact that the serial correlations for aggregate stock returns are weak especially in the recent decade, the quest for additional predictors goes on. Many financial variables have been shown to possess predictive power for stock returns. A partial list of these variables can be characterized as variables that

are related to interest rates: relative interest rate [7], term spread and the default spread [7, 16, 23], inflation rate [14, 18]; variables that are related to “one over the price”: dividend yield [10], payout yield [4], earning–price ratio and dividend–earnings (payout) ratio [26], book-to-market ratio [25, 32]; and other variables including aggregate net issuing activity [2] and consumption–wealth–income ratio [27].

Although the focus is on the rational explanation for predictability, the evidence has also been interpreted differently under different views. Their differences are illustrated by the following story. Once there were four students walking on a street with their professor. A dollar bill lying on the sidewalk quickly caught the professor’s eyes. The professor asked the four students why nobody was picking up the dollar bill. The first student answered although the dollar bill was real, people just pretended not seeing it. The second student argued that the dollar bill was just an illusion (or a statistical illusion). The third student said that, even though the dollar bill was real, no one would bother to pick it up because it was too costly to pick it up (or transactions costs). The last student’s answer was that the dollar bill was real. Someone left it there for a needy person. Generally speaking, the first student is a behaviorist; the second and third students hold the traditional efficient market view; and the last student holds the modern view on the EMH. No matter which student’s answer represents your view, predictability cannot be too large. There is an old saying: if you can predict the market, why aren’t you rich!

The existence of predictability is crucial in testing the conditional asset pricing models [19], in return decomposition [8], in asset allocation [22], and so on. Because of the theoretical foundation for predictability, this article focuses primarily on aggregate market returns. Predictability is also related to anomalies. An anomaly is defined as the deviation from an asset pricing model. In most empirical studies, anomalies are tied to a specific part of the market, such as small firms, firms with low book-to-market ratios, and so on, or particular sample periods, such as January, weekends, and so on. A detailed review on anomalies can be found in [35].

This article intends to offer a perspective on both the evidence and the reasons for return predictability. A detailed discussion about the economic reasons for predictability is given in the section Economic Interpretation of Predictability. Recent empirical studies

have uncovered many useful predictors, which are summarized in the section Understanding Some Useful Predictors. Predictability is not without controversy. Many of the statistical issues in testing the predictability are discussed in the section Statistical Issues, followed by conclusion in the last section.

Evidence on Predictability

The most simple form of predictability is the return autocorrelation. To gain a perspective on the magnitude of the serial correlation, returns of different frequencies and over different sample periods are examined. Owing to the availability of daily returns, the whole sample period is from 1962 to 2006. The summary statistics is listed in Table 1 for both value-weighted and equal-weighted NYSE/AMEX/NASDAQ composite index returns.

For the whole sample period, the average value-weighted index daily return is 0.044% with a volatility of 0.859%. Such a large difference between average return and volatility implies a very low Sharpe ratio of 5%. If returns are autocorrelated, the “true” Sharpe ratio should be larger.^a For the value-weighted index returns, the autocorrelation is about 13%. Such a large autocorrelation further increases to 31% when an equal-weighted index is used. If we fit an $AR(1)$ model to the equal-weighted index returns, we see an R^2 of 9.61%! The autocorrelation difference in the two types of index returns suggests that small stocks are more predictable than large stocks. To see whether such a predictability is stable over time, the whole sample period is split into two. From Table 1,

it is clear that most of the predictability from past returns concentrates in the early sample period from 1962 to 1984, with autocorrelations as high as 22.4 and 38.5% for value-weighted and equal-weighted indices, respectively.

Predictability in daily returns might be subject to market microstructure effects discussed in the section The Economic Interpretation of Predictability. One way to alleviate such effects is to examine the behavior of monthly returns. For both value- and equal-weighted index returns, the autocorrelations have been substantially attenuated. For example, over the whole sample period, autocorrelation for value-weighted index returns is only 4.3%, almost negligible. For the equal-weighted index, however, the autocorrelation is still as large as 17.6% for the whole sample period and is stable over the two subsample periods. Therefore, it can be concluded that return serial correlations are more likely to occur in small stocks. Given there are still substantial serial correlations in low-frequency small stock return data, market microstructure effects cannot be the only factor.

If future returns can only be weakly predicted by past returns, are there other variables that help to predict returns? In Table 2, we further study return predictability using three other variables—the dividend yield, the repurchasing yield, and the relative interest rate. Our sample starts in 1952 after a major shift in the interest rate regime by the Federal Reserve. To be representative, we focus on the value-weighted index returns. During the first 17 years from 1952 to 1978, both the dividend yield and the relative interest rate

Table 1 Autocorrelations in index returns

Sample period	Value weighted			Equal weighted		
	Mean	SD	Corr.	Mean	SD	Corr.
Panel A: daily returns						
1962–2006	0.044	0.859	13.2	0.069	0.744	31.0
1962–1984	0.035	0.794	22.4	0.068	0.787	38.5
1985–2006	0.053	0.922	6.1	0.071	0.696	21.0
Panel A: monthly returns						
1962–2006	0.929	4.216	4.3	1.186	5.345	17.6
1962–1984	0.772	4.422	6.0	1.285	6.252	16.4
1985–2006	1.079	4.010	1.9	1.092	4.312	20.0

This table reports the characteristics of NYSE/AMEX/NASDAQ composite index returns over different samples periods and for different frequencies. “Corr.” stands for the first-order autocorrelation; “SD” is the standard deviation

Table 2 VAR results for index returns

Dependent variable	r_t	$(D/P)_t$	$(F/P)_t$	$rrel_t$	Adjusted R^2
Panel A: sample period 1952–1978					
r_{t+1}	0.061	10.90	0.675	−11.67	0.062
$(D/P)_{t+1}$	−0.000	0.966	0.003	0.042	0.956
$(F/P)_{t+1}$	−0.001	0.038	0.943	0.034	0.898
$rrel_{t+1}$	0.000	0.032	0.005	0.731	0.529
Panel A: sample period 1979–2005					
r_{t+1}	0.030	0.461	3.508	−0.801	0.009
$(D/P)_{t+1}$	−0.000	0.994	−0.009	0.005	0.985
$(F/P)_{t+1}$	−0.001	0.029	0.971	0.071	0.960
$rrel_{t+1}$	−0.000	0.009	−0.010	0.751	0.560

This table reports the VAR results for the four variables including the value-weighted NYSE/AMEX/NASDAQ composite index return, dividend yield, repurchasing yield, and the relative interest rate over different sample periods. The bold face number indicates that the estimate is statistically significant at a 5% level

have helped to predict returns, with an adjusted R^2 of 6.2%. In contrast, the repurchasing yield becomes more important over the next 17 years from 1979 to 2005, with an adjusted R^2 of 0.9%. The evidence suggests that returns are predictable even if not by their past returns. Despite large persistence of all three predictors as shown in Table 2, statistical adjustment for estimates will not likely take away the predictive power of the three variables (see the section Statistical Issues).

Predictability and Market Efficiency

Historically, predictability has been associated with market inefficiency. According to the fundamental law of valuation, a security price should reflect its expected fundamental value for risk-neutral investors with zero interest rate:

$$P_t = E[V^*|\mathcal{I}_t], \quad P_{t+1} = E[V^*|\mathcal{I}_{t+1}] \quad (1)$$

where V^* is the fundamental value and $\mathcal{I}_t$ is the information set at time t . Since the information set $\mathcal{I}_t$ is included in the information set $\mathcal{I}_{t+1}$, the following result is obtained by the law of iterated expectations:

$$P_t = E[V^*|\mathcal{I}_t] = E[E(V^*|\mathcal{I}_{t+1})|\mathcal{I}_t] = E[P_{t+1}|\mathcal{I}_t] \quad (2)$$

Equation (2) suggests that security prices should follow a Martingale process.^b The best predictor for

future prices is the current price. In other words, we have

$$\text{Cov}[(P_{t+j} - P_{t+i}), (P_{t+l} - P_{t+k})|\mathcal{I}_t] = 0 \quad (3)$$

where $i < j < k < l$. In other words, the nonoverlapping price changes are uncorrelated at all leads and lags. If we interpret the price difference as a return, it means that returns should be unpredictable.

This analysis defines the notion of EMH. Financial markets are said to be efficient if security prices *rapidly* reflect *all* relevant information about asset values, and all securities are *fairly priced* in light of the available information. In other words, the EMH describes how security prices should react to available information and how prices should evolve over time. Under this framework, return predictability serves as evidence against the EMH.

Does the EMH indeed exclude predictability? To answer this question, we focus on a stronger version of the Martingale process, which is the random walk process, and assume that investors are risk averse. The random walk process was first used by Bachelier (1900) to model stock prices in his dissertation, and was rekindled by Merton in the late 1960s. For convenience, we use log price p_t

$$p_{t+1} = \mu + p_t + \epsilon_{t+1} \quad (4)$$

where μ is the expected price change. If we define return as $r_{t+1} = p_{t+1} - p_t$, equation (4) can be expressed as

$$r_{t+1} = \mu + \epsilon_{t+1} \quad (5)$$

Strictly speaking, the EMH only puts a restriction on the residual ϵ_{t+1} to satisfy the condition of $E[\epsilon_{t+1}|I_t] = 0$ at any time t in either equation (4) or (5). Since μ is determined by an asset pricing model, such as the CAPM, the traditional view on the *EMH* implicitly assumes that μ is constant. The modern finance theory, however, has offered a different view on μ . For example, Fama and French [17] have suggested that the risk premium might be higher in the economic downturn than in the peak of a business cycle. This evidence suggests that the expected return might be time varying. In fact, many asset pricing models since Merton have emphasized the idea of changing investment opportunities, which requires additional risk compensation over time. Alternatively, investors' risk tolerance might change over time, which will cause the investors to demand different levels of risk premium. No matter which scenario is more likely, one should allow μ to be time varying:

$$r_{t+1} = \mu_{t+1} + \epsilon_{t+1} \quad (6)$$

Although under the EMH, we still have the condition of $E[\epsilon_{t+1}|I_t] = 0$, $E[\mu_{t+1}|I_t]$ is not necessarily constant. For example, if risk premia changes with the business cycle and the business cycle is predictable, return should also be predictable. This analysis opens a channel for the predictability to coexist with the EMH.

Returns from a buy-and-hold strategy on the market portfolio correspond to returns for a representative investor. Predictability means that someone can implement a trading strategy that requires a full investment in some periods and a zero or a short position in other periods in order to earn higher returns than those from a buy-and-hold strategy. Clearly, this investment strategy cannot be implemented by the representative investor since he/she has to fully invest in the equity market. Although such a strategy will pay off in a long run, it is not without risk in short term. The success of this strategy depends on the degree of predictability. Therefore, predictability cannot be too large in order to prevent too many investors defecting from being representative investors.

The Economic Interpretation of Predictability

Without assuming irrationality and market inefficiency, how can we interpret predictability under the

traditional framework? Most explanations focus on market microstructure effects and transactions costs. This section reviews the bid-ask bounce, nonsynchronous trading, and transactions costs in explaining the return autocorrelation.

Bid-ask Bounce

Returns tend to be negatively autocorrelated in a short-run. One possible explanation is offered by Roll [34] from the perspective of bid and ask price differences. In the absence of information, sell orders and buy orders arrive with the same probabilities. In other words, a buy order is likely to follow a sell order, which results in a negative autocorrelation. In particular, let P_t^* be the fundamental value:

$$P_t = P_t^* + I_t(s/2) \quad (7)$$

$$I_t = \begin{cases} +1 & \text{if buy order with prob} = 0.5 \\ -1 & \text{if sell order with prob} = 0.5 \end{cases} \quad (8)$$

where s is the bid-ask spread. This implies a price change of $\Delta P_t = \Delta P_t^* + (I_t - I_{t-1})s/2$. In other words, autocorrelation is related to the spread s in the following way:

$$\text{Cov}(\Delta P_{t-1}, \Delta P_t) = -s^2/4 \quad (9)$$

Since the bid-ask spreads tend to be larger for small company stocks than for large stocks, autocorrelation will be stronger for small firms than for large stocks, other things being equal. Equation (9) can also be used to back out the implied bid-ask spread.

If the autocorrelation is due to differences in the bid and ask prices, the effect should be smaller if the average bid and ask prices are used to compute returns instead of the actual closing prices. Similarly, low-frequency returns, such as monthly returns, should have weaker autocorrelation than high-frequency returns, such as daily returns, which is true in general. We should also see a drop in autocorrelations over time when the average bid-ask spread shrinks, especially after decimalization. This is confirmed in Table 1. In general, investors cannot design a trading strategy to obtain excess returns in this case, since the bid and ask effect is due to the market friction.

Nonsynchronous Trading

Although individual stock returns might exhibit negative serial correlation, portfolio returns tend to be positively autocorrelated. Lo and MacKinlay [29] have offered “nonsynchronous trading” as a mechanism in generating such a positive autocorrelation. In practice, not all stocks, especially small stocks, are traded at any given moment. On the arrival of market wide news, these stocks that are not traded currently will have similar returns to those traded today when trading resumes next period, which will make the portfolio with all stocks look like autocorrelated.

To illustrate the idea, suppose that there are two stocks A and B following random walk processes, implying no autocorrelation in their own returns. At the release of a market wide news at time $t = 0$, we would have observed returns of R_1^A and R_1^B for stocks A and B , respectively. Owing to the commonality of the news, we assume $\text{Cov}(R_1^A, R_1^B) > 0$. If stock A is not traded and stock B is traded, however, we will only observe $\hat{R}_1^A = 0$ and $\hat{R}_1^B = R_1^B$. Similarly, there is a common news released at $t = 1$. Both stocks are traded this time, resulting in returns of R_2^A and R_2^B for the two stocks. Owing to the random walk assumption on individual stocks, we have $\text{Cov}(R_1^A, R_2^A) = 0$ and $\text{Cov}(R_1^B, R_2^B) = 0$. This structure can be summarized as follows:

$$\begin{array}{ccccccc} \text{Stock A :} & | & \hat{R}_1^A = 0 & | & \hat{R}_2^A = R_1^A + R_2^A & | & \\ \text{Stock B :} & | & \hat{R}_1^B = R_1^B & | & \hat{R}_2^B = R_2^B & | & \\ & & t = 0 & & t = 1 & & t = 2 \end{array} \quad (10)$$

Now, consider an equal-weighted portfolio of the two stocks. The portfolio returns in the two periods are $\hat{R}_1^P = \frac{1}{2}R_1^B$ and $\hat{R}_2^P = \frac{1}{2}(R_2^B + R_1^A + R_2^A)$. It is easy to see that $\text{Cov}(\hat{R}_1^P, \hat{R}_2^P) = \frac{1}{2}\text{Cov}(R_1^A, R_1^B) > 0$. The same idea applies to the case when different stocks are traded at different times. Using daily returns from 1962 to 1985 to form 20 size portfolios, Lo and MacKinlay reported the following first-order autocorrelations and the probability of nontrading (Table 3):

Clearly, a large autocorrelation of 35% in small stock portfolio returns can be supported by a 29% likelihood of nontrading in small stocks.^c However, it is difficult to justify the 17% autocorrelation in large stock portfolio returns by the corresponding likelihood of nontrading. In addition, the cross autocorrelation of 33% from the large stock portfolio to the small stock portfolio is also consistent with

Table 3 The probability of nontrading; adopted from Lo and Mackinlay [29]

$t t + 1$	Small	Medium	Large	Probability nontrading
Small	0.35	0.21	0.02	0.291
Medium	0.39	0.31	0.09	0.025
Large	0.33	0.36	0.17	0.008

the nontrading in small stocks. Under this view, no money can be made even with a positive return autocorrelation.

Transactions Costs

Nontrading is a bit of an econometrics device. Instead, security prices could be slow to update in the arrival of information due to transactions costs. In other words, transactions costs put a wedge in how prices might change over time. Let P_t^* be investors' correct valuation. They will trade only when the price cover the transactions costs. In other words, there will be a bound around the current price. Only when P_t^* accumulates to the degree that overcomes the bound, we will see a price change. Otherwise, there will be zero excess demand within the bound. Such a slow adjustment will create a positive autocorrelation in security returns.

Cross Autocorrelation

The evidence of large stock returns predicting small stock returns seems to be persuasive since it existed in both daily and monthly stock returns. Although one might attribute the phenomenon to the nonsynchronous trading story on the daily frequency, nontrading is less likely for monthly returns. In response, Boudoukh *et al.* [5] offered an alternative explanation that utilizes the serial correlation and the contemporaneous correlation to explain the cross correlation.

Suppose that security i 's return follows an $AR(1)$ process of the following form:

$$r_{i,t+1} = \mu + \theta r_{i,t} + \epsilon_{i,t+1} \quad (11)$$

It is easy to see that $\theta = \text{Corr}(r_{i,t+1}, r_{i,t})$. Multiplying both sides of equation (11) by $r_{j,t}$ and assuming that $\text{Cov}(\epsilon_{i,t+1}, r_{j,t}) = 0$, we have the following relation:

$$\text{Corr}(r_{i,t+1}, r_{j,t}) = \text{Corr}(r_{i,t+1}, r_{i,t})\text{Corr}(r_{i,t}, r_{j,t}) \quad (12)$$

Table 4 Portfolio correlations adopted from Boudoukh *et al.* [5]

Portfolio	Small _{t+1}	Medium _{t+1}	Large _{t+1}	Small _t	Large _t
Small _t	0.36	0.19	0.03		
Medium _t	0.35	0.22	0.06	0.89	
Large _t	0.28	0.21	0.07	0.72	0.91

This table reports cross- and auto-correlations among size portfolios

As seen from equation (12), the cross autocorrelation is essentially the self-autocorrelation acted on contemporaneous correlation. Using a different sample period, Boudoukh *et al.* [5] found that results are consistent with equation (12) (Table 4).

Applying equation (12), we can compute the predicted cross autocorrelations as

$$\begin{aligned}
& \text{Corr}^*(r_{\text{small},t+1}, r_{\text{large},t}) \\
&= \text{Corr}(r_{\text{small},t+1}, r_{\text{small},t}) \text{Corr}(r_{\text{small},t}, r_{\text{large},t}) \\
&= 0.36 \times 0.72 = 0.26
\end{aligned} \tag{13}$$

$$\begin{aligned}
& \text{Corr}^*(r_{\text{large},t+1}, r_{\text{small},t}) \\
&= \text{Corr}(r_{\text{large},t+1}, r_{\text{large},t}) \text{Corr}(r_{\text{large},t}, r_{\text{small},t}) \\
&= 0.07 \times 0.72 = 0.05
\end{aligned} \tag{14}$$

These numbers are very close to the actual cross autocorrelations shown in the table. Therefore, we do not need frequent nontrading to justify the observed cross autocorrelation. However, we still need to understand the serial correlation.

Time-varying Expected Returns

The mechanism for the observed autocorrelation, discussed in the previous sections, largely relies on market frictions. As discussed in the section Predictability and Market Efficiency, an alternative rational explanation for predictability is the time-varying expected return. Given the unobservability nature of expected returns, Conrad and Kaul [13] proposed to characterize the movement in expected returns as following a simple $AR(1)$ process of

$$r_{t+1} = E_t(r_{t+1}) + \epsilon_{t+1} \tag{15}$$

$$E_t(r_{t+1}) = \bar{r} + \phi E_{t-1}(r_t) + u_t \tag{16}$$

Note that the coefficients in equations (15) and (16) can be estimated using the Kalman filter procedure. Testing the hypothesis of time-varying expected return is equivalent to test whether $\phi = 0$ in the above models. Using the 10 size-sorted weekly (Wednesday to Tuesday) portfolio returns from 1962 to 1985, Conrad and Kaul [13] found that the autocorrelations coefficients are 41 and 9% for the small and the large decile portfolios, respectively, which are both statistically significant when compared to the confidence bound of $1/\sqrt{T} = 0.03$. Although the persistence parameter estimates ($\hat{\phi}$) of 0.589 and 0.087 for small and large portfolios, respectively, are very different, they are statistically significant at a 1% level.

It is important to understand why expected returns change over time. In the CAPM world, it is implicitly assumed that a firm will continue to produce the same widgets and face the same uncertainty when selling these widgets in the market. In other words, the risk structure in future cash flows (CFs) is fixed. Thus, the comovement with the overall market is fixed. At the same time, investors' attitude toward risk does not change, which implies constant expected returns. Such a model structure may reasonably describe the real world over a short period of time.

Over a longer horizon, however, investment opportunities can change due to either technological advances or changes in consumers' preference toward goods and services. For example, Apple used to be in the business of making personal computers and software 10 years ago. Today, a significant portion of Apple's business is in the consumer electronics including music players and cell phones. Under this view, both the risk environment of a firm and the risk tolerance of investors could change over time. Therefore, the observed predictability may simply provide compensation for investors' exposure to the risk of change in investment opportunities or reflect the differences in the required risk compensation due to change in the risk tolerance over different economic conditions. In this case, a representative investor will not try to utilize the predictability to alter his/her asset allocations. For example, if he/she knows that the next period stock return will likely be high, he/she should allocate more assets to stocks. However, if he/she understands that the high return is associated with high expected return due to his/her increased risk aversion next period,

he/she would not increase his/her holding of the risky stocks.

Understanding Some Useful Predictors

In an interesting paper by Boudoukh *et al.* [5], it is argued that the observed autocorrelation in returns neither is due to market inefficiency nor can be attributed to time-varying expected returns. If autocorrelation in the returns of an index, such as the *S&P500*, is due to market inefficiency or time-varying expected returns, the same autocorrelation should be observed in the *S&P500* future contract returns too, but they did not find supportive evidence.^d This result seems to kill the predictability associated with autocorrelation, but does not necessarily provide evidence against other form of predictability. Moreover, autocorrelation in returns is a sufficient condition for predictability. It is not a necessary condition. There could exist nonreturn-based predictors. Suppose that the return generating process is as follows:

$$r_{t+1} = \beta z_t + \epsilon_{t+1} \quad (17)$$

where z_t is a predictor with $\text{Cov}(z_t, \epsilon_{t+1}) = 0$ and $\text{Cov}(\epsilon_t, \epsilon_{t+1}) = 0$. Since $\text{Cov}(r_{t+1}, r_t) = \beta \text{Cov}(z_t, r_t) + \text{Cov}(\epsilon_{t+1}, r_t) \approx \beta \text{Cov}(z_t, r_t)$, autocorrelation could be close to zero as long as $\text{Cov}(z_t, r_t)$ is small, which is usually the case.

Therefore, recent literature has focused its attention on predictors other than past returns. For example, an incomplete list includes short-term interest rate, term spread, default spread, inflation rate, dividend yield, book-to-market ratio, consumption–wealth–income ratio, repurchasing yield, and so on. It is important to know why these variables predict returns in the first place. Without theory, a variable found to be useful in predicting stock returns could be a result of data mining.

A closer look at these predictors reveals that they are either related to business cycles or associated with stock prices. Since expected returns could vary with business cycles, variables that predict business cycles such as the term spread or the default spread should be useful predictors. Many significant predictors, such as the dividend yield, book-to-market ratio, and repurchasing yield, contain the element of one over price. This common feature comes from the fact

that security prices reflect investors' expectations, and expectations are good predictors of future values. To further illustrate this rationale, we can use mathematical models to relate returns to prices or other variables.

The Dividend–price Ratio—Log-linearization

Perhaps the most frequently used predictor is the dividend–price ratio or the dividend yield. This is also the variable that has been scrutinized the most [1]. Despite many statistical issues discussed in the following section, it is important to understand why the dividend–price ratio should predict future returns. We start from the following return identity:

$$R_{t+1} = \frac{P_{t+1} + D_{t+1}}{P_t} = \frac{P_{t+1}}{D_{t+1}} \frac{D_t}{P_t} \frac{D_{t+1}}{D_t} \left[1 + \frac{D_{t+1}}{P_{t+1}} \right] \quad (18)$$

It is difficult to allow time-varying expected return due to the nonlinearity in equation (18). We, thus, take natural log on both sides of equation (18) and apply Taylor series expansion around the steady state. After simplifying [8], we obtain the following equation:

$$d_t - p_t = \text{const} + \rho(d_{t+1} - p_{t+1}) + r_{t+1} - \Delta d_{t+1} \quad (19)$$

where $\rho = 1/(1 + D/P) = 1/1.04 = 0.96$ (with D/P being the steady-state dividend–price ratio), $\Delta d_{t+1} = d_{t+1} - d_t$, and lowercase variables represent log of the corresponding uppercase variables. Under the assumption of stationary dividend–price ratio, we can solve equation (19) forward,

$$d_t - p_t = \text{const} + \sum_{j=0}^{\infty} \rho^j (-\Delta d_{t+1+j} + r_{t+1+j}) \quad (20)$$

Equation (20) implies that a high dividend–price ratio must mean either a low future dividend growth or a high future return. In addition, dividends and returns that are closer to the present are more influential than dividends and returns far in the future due to the fact that ρ is less than 1.

From an empirical perspective, we can compute the volatility of dividend–price ratio by multiplying both sides of equation (20) by $(d_t - p_t)$

$$\begin{aligned} \text{Var}(d_t - p_t) = & -\text{Cov}\left(d_t - p_t, \sum_{j=0}^{\infty} \rho^j \Delta d_{t+1+j}\right) \\ & + \text{Cov}\left(d_t - p_t, \sum_{j=0}^{\infty} \rho^j r_{t+1+j}\right) \quad (21) \end{aligned}$$

Since the volatility of $(d_t - p_t)$ is positive, it is clear that the dividend–price ratio will forecast either dividend growth or future returns. Empirical evidence suggests that the $(d - p)$ variable does not forecast future dividend growth. Therefore, the $(d - p)$ ratio must forecast future returns. Again, such a predictability does not imply market inefficiency in predicting ϵ_{t+1} in equation (6). A testing strategy based on equation (21) is to regress the sum of future returns on the dividend–price ratio:

$$r_{t+1} + \dots + r_{t+\tau} = \alpha + \beta(\tau)(d_t - p_t) + \epsilon_{t+1,t+\tau} \quad (22)$$

where τ is the number of future periods. Table 5 is adapted from Campbell *et al.* [9] on monthly

NYSE/AMEX/NASDAQ composite index returns. Clearly, the degree of predictability measured by R^2 increases monotonically with the return horizon. For example, R^2 s are 0.7, 8.6, 21.7, and 41.9% over 1 month, 1 year, 2 years, and 4 years, respectively, in the early sample period of 1927–1951. Similarly, R^2 s continue to be impressive with 1.8, 18.8, 32.2, and 41.7% over 1 month, 1 year, 2 years, and 4 years, respectively, in the later sample period from 1952 to 1994.

Issues with Long-horizon Regressions

Long-horizon regressions, such as equation (22), were first advocated by Fama and French [15]. Despite the impressive magnitude of R^2 s, the power of the associated long-horizon tests is doubtful. The issue involves the use of overlapping observations due to the availability of data [33]. In general, overlapping samples could lead to large efficiency gains when the independent variables in a predictive regression are serially uncorrelated. However, most predictors are highly autocorrelated, which implies limited efficiency gains when using overlapping observations. For example, for the 60 years of returns used in the Fama and French [15] study, although the nominal sample size is large using overlapping returns, the effective sample size is not much larger than 12

Table 5 Long-horizon results for index returns

Forecast horizon	1 Month	3 Months	12 Months	24 Months	48 Months
Panel A: sample period 1927–1994					
$\beta(\tau)$	0.016	0.043	0.200	0.386	0.654
$t(\tau)$	1.553	1.420	2.257	4.115	3.870
$R^2(\tau)$	0.007	0.014	0.073	0.143	0.261

$\beta(\tau)$	0.027	0.080	0.327	0.579	0.843
$t(\tau)$	3.118	3.152	3.181	3.072	3.508
$R^2(\tau)$	0.018	0.049	0.188	0.322	0.417

This table reports results from regressing future τ months returns on current dividend–price ratio for the value-weighted NYSE/AMEX/NASDAQ composite index return. The regression model is given as follows:

$$r_{t+1} + \dots + r_{t+\tau} = \alpha + \beta(\tau)(d_t - p_t) + \epsilon_{t+1,t+\tau}$$

(the nonoverlapping 5-year sample) due to the highly persistent regressor. As pointed out by Boudoukh *et al.* [6], if an innovation in an independent variable happens to coincide with the next period return, this relationship will be repeated many times in the long-horizon regression since the shock will not die out for many periods and the particular return will appear many times in the overlapping return series.

Under the null hypothesis of no autocorrelation in returns, that is, $\beta(\tau) = 0, \forall \tau$ in equation (22), Kirby [24] has shown the following asymptotic result for the R^2 from a predictive regression:

$$T \times R^2 \xrightarrow{d} \chi^2(K) \quad (23)$$

where T is the number of observations and K is the number of independent variables in the regression. Let us use a numerical example to illustrate the point. For a univariate regression with $K = 1$ and $T = 12$, what would we expect to see?

- Since the mean of a $\chi^2(1)$ random variable is 1, we have $E(12R^2) = 1$, which implies that $E(R^2) = 8.3\%$.
- The 95% cutoff for R^2 is expected to be 32% since the critical value for a $\chi^2(1)$ distribution under the same confidence level is 3.84. In other words, we can expect to see R^2 s as high as 32% even though there is no predictability.

Therefore, long-horizon regression results are avoided in this article.

The Payout Ratio or the Repurchasing Yield

Recently, Boudoukh *et al.* [4] have proposed to use the total payout ratio as a predictor for stock returns. The importance of the new predictor can be illustrated by its impressive R^2 of 26% using annual data over the sample period from 1926 to 2003. The use of payout ratio can be justified since investors' total wealth could also be affected by share repurchasing. In fact, representative investors should care about the total distribution, which includes both the direct dividend distributions and repurchases. If there are rational reasons to believe that dividend yield predicts stock returns, the payout yield should play a similar role. In fact, the implementation of the SEC rule 10b-18 in 1982 gives firms an incentive to rely more on repurchases due to the tax advantages for investors.

Payout Ratio. Repurchasing could be used either to reduce the effect of stock option exercise or to substitute for dividends. To construct a measure that reflects the latter, Boudoukh *et al.* [4] used change in treasury stock adjusted for potential asynchronicity between the repurchase and option exercise as a measure of repurchasing (TS). They also used total repurchasing from the CF statement. Results are summarized in Table 6. Clearly, the predictive power of the dividend-price ratio (D/P) has gone down when comparing R^2 s from the two sample periods. In particular, R^2 has decreased from 13 to 8% when including the recent sample period.

Table 6 Dividend yield and payout ratio

	$\ln(D/P)$	$\ln(CF/M)$	$\ln(TS/M)$	$\ln(0.1 + \text{Net payout})$
1926–2003				
Coef	0.116	0.209	0.172	0.759
t -ratio	2.240	3.396	2.854	5.311
R^2	0.055	0.091	0.080	0.262
Sim p -value	0.083	0.011	0.020	0.000
1926–1984				
Coef	0.296	0.280	0.300	0.794
t -ratio	3.666	3.688	3.741	5.342
R^2	0.130	0.121	0.135	0.300
Sim p -value	0.044	0.054	0.043	0.001

This table reports results from predictive regressions using various predictors. “CF/M” is the total repurchasing from cash flow statement (CF) over the total market value, while “TS/M” is change in treasury stock adjusted for potential asynchronicity between the repurchase and option exercise as a measure of repurchasing (TS) over the total market value. “ D/P ” is the usual dividend-price ratio for the value-weighted NYSE/AMEX/NASDAQ composite index

Table 7 The adjusted R^2 s for predictive regression using the dividend yield (D/P) and/or the repurchasing yield (F/P) over different sample periods

Frequency	1952–2005		1952–1978		1979–2005	
	D/P	F/P	D/P	F/P	D/P	F/P
Monthly	0.5	1.0	1.9	0.0	0.0	1.7
Quarterly	1.9	2.5	5.6	0.0	0.7	5.6

In contrast, the repurchasing yield (measured as the ratio between repurchasing and market capitalization) is impressive. No matter how it is measured, the explanatory power is much larger than the pure dividend–price ratio. Moreover, when using the net payout yield (measured as the ratio between repurchasing minus new issuing plus dividend and the market capitalization), R^2 is as high as 26%. Although the payout yield is important empirically, its significance is overstated in Boudoukh *et al.* [4]. The most significant contributor to the predictive power of the payout yield is the new issuing yield when examining their accounting-based measures separately. Furthermore, the predictive power of new issuing yield largely comes from the two outliers of 1929 and 1930. In other words, the new issuing yield offers no explanatory power once the sample period starts from 1931 instead of 1926.

An Alternative Approach to Construct the Repurchasing Yield. The conventional approach of computing returns ignores changes in the market capitalization associated with changes in the total number of share outstanding. When the number of shares changes over time due to either repurchasing or seasonal offering, capital gains do not purely reflect growth potential. From an asset pricing perspective, it is more important to consider different components of returns from a representative investor’s perspective. In other words, we can decompose returns from the stand point of a representative investor instead of a buy-and-hold investor. In particular, we can rewrite the return identity as the following:

$$R_{t+1} \equiv \frac{S_{t+1}D_{t+1}}{S_t P_t} + \frac{(S_t - S_{t+1})(P_{t+1} + D_{t+1})}{S_t P_t} + \frac{S_{t+1}P_{t+1}}{S_t P_t} \quad (24)$$

where S_t is the number of share outstanding at time t . Equation (24) can be interpreted in the following way:

- *first term*: dividend yield (D/P) for a representative shareholder;
- *second term*: net repurchasing yield (F/P) at the before ex-dividend day price; and
- *third term*: change in market capitalization, which reflects growth.

Using NYSE/AMEX/NASDAQ index returns, we can construct both the smoothed dividend yield (D/P) and the repurchasing yield (F/P) over the past 12 months. Table 7 reports the adjusted R^2 s for various predictive regressions.

For the whole sample period from 1952 to 2005, quarterly returns are more predictable than monthly returns. Overall, the repurchasing yield has higher predictive power than the dividend yield. When we split the sample into two, it becomes clear that the two predictors have played very different roles. Almost all the predictive power in the first half of the sample comes from the dividend yield, whereas majority predictive power in the second half of the sample is due to the repurchasing yield. This evidence is consistent with the observation of a decreasing trend in the dividend yield and the increasing role played by repurchases.

Statistical Issues

The use of many predictors can be controversial. In many cases, the issue lies in the statistical inference due to the persistence in predictors. These issues include spurious regression, biased estimates due to correlations between innovations to predictors and stock returns, and error in variables when using imperfect predictors.

Spurious Regression

When regressing one nonstationary random variable on another independent nonstationary random variable, we often observe a significant relationship between the two variables. This is because, in a finite sample, both variables are likely to be perceived trending. Spurious regression is first discussed by Granger and Newbold [21]. At a first glance, spurious regression may not seem to be likely for a predictive regression since stock returns on the left-hand side of a regression are not persistent at all. However, if we consider stock returns as containing a persistent expected return component, the predictive regression could be spurious [20]. This problem can even be more severe when researchers are mining for predictors because highly persistent series are more likely to be found significant in the search for predictors. Their simulation results suggest that many of the useful predictors found in the literature could be subject to this criticism.

Predictive Regression

Owing to persistence in the predictors and a correlation between innovations to predictors and stock returns, Stambaugh [36] has suggested that both the coefficient estimate and the t -ratio in a predictive regression are biased. For example, when the current stock price is high, the current return will also be high, whereas the current dividend-price ratios will be low since the D/P ratio has a price in the denominator. Such an association implies a negative relationship between innovations to D/P ratios and innovations to returns. Such a negative correlation will couple with the typical downside bias in the persistence parameter estimate of the D/P ratio to make the predictive regression coefficient bias upward. More specifically, suppose that we have the following system:

$$r_{t+1} = \beta z_t + \epsilon_{t+1} \quad (25)$$

$$z_{t+1} = \psi z_t + u_{t+1} \quad (26)$$

where z_t is the predictor. It can be shown [28] that

$$E(\hat{\beta} - \beta) = \gamma(\hat{\psi} - \psi) \quad (27)$$

where γ is from the regression of $\epsilon_t = \gamma u_t + v_t$. Since γ is negative in the case of dividend-price

ratio and $\hat{\psi}$ is typically biased downward, equation (27) suggests that the beta estimate is biased upward. Therefore, Stambaugh concluded that the predictive power of dividend yield is exaggerated.

While Stambaugh's bias adjustment is based on the well-known bias result of $\hat{\psi}$ being $-(1 + 3\psi)/T$, Lewellen [28] observes that such a bias typically occurs in the data that appear to mean-revert more strongly than they truly do. However, predictors such as the dividend yield are hardly mean-reverting. They contain roots very close to unity. Instead, Lewellen [28] proposed to use $\psi = 1$ as the true value in equation (27) in order to derive a conservative adjustment. For example, using NYSE returns and log dividend-price ratio over the ample period from 1946 to 2000 in equation (25), the least-squares estimate of β is 0.92, with a standard error of 0.48. When applying Stambaugh [36] bias correction, the estimate becomes 0.20 with a one-sided p -value of 0.308. In contrast, using Lewellen's conservative bias adjustment, the estimate becomes 0.66 with a t -ratio of 4.67.

Implied Constraint

To push the idea of incorporating prior knowledge as in Lewellen [28], Cochrane [12] argued that the coefficients from predictive regressions of returns, dividend growth, and dividend-price ratio using the lagged dividend-price ratio should be constrained. In particular, if we run the following regressions,

$$r_{t+1} = a_r + b_r(d_t - p_t) + \epsilon_{r,t+1} \quad (28)$$

$$\Delta d_{t+1} = a_d + b_d(d_t - p_t) + \epsilon_{d,t+1} \quad (29)$$

$$d_{t+1} - p_{t+1} = a_{dp} + \psi(d_t - p_t) + \epsilon_{dp,t+1} \quad (30)$$

the regression coefficients b_r , b_d , and ψ should be related. In fact, by substituting equations (28) through (30) into equation (19), we have the following results:

$$b_r = 1 - \rho\psi + b_d \quad (31)$$

$$\epsilon_{r,t+1} = \epsilon_{d,t+1} - \epsilon_{dp,t+1} \quad (32)$$

Since $\rho < 1$ and $\psi < 1$, equation (31) implies that one cannot test the joint hypothesis of $b_r = 0$ and $b_d = 0$ at the same time. In other words, if we fail to reject the hypothesis of $b_d = 0$, we cannot ignore the evidence that b_r is positive in the predictive

Table 8 The actual parameter estimates and the implied parameters; adopted from Cochrane [12]

	Estimates	$\sigma(\hat{b})$	Implied value	Correlation		
				ϵ_r	ϵ_d	ϵ_{dp}
$\hat{b}_r$	0.097	0.050	0.101	ϵ_r	19.6	66.0 -70.0
$\hat{b}_d$	0.008	0.044	0.004	ϵ_d	66.0	14.0 7.5
$\hat{\psi}$	0.941	0.047	0.945	ϵ_{dp}	-70.0	7.5 15.3

regression of equation (28). As shown in Table 8 (adapted from [12]), the $\hat{b}_d$ estimate is very close to zero with a large standard error. Therefore, b_r is probably close to 0.101 as implied by equation (31) using $\rho = 0.9638$, which is close to the actual estimate of 0.097.

At the same time, equation (32) suggests that shocks to returns and the dividend-price ratio are highly correlated with each other, which are indeed true from Table 8. For example, the negative correlation is as high as 70%. Table 8 also shows that the estimated coefficients b_r , b_d , and ψ and their corresponding implied values from equation (31) are amazingly close.

Error in Variables

If predictability is driven by time-varying expected returns, predictors should predict the expected return. In other words, the conventional predictive regression implicitly assumes that the expected return is a linear function of the predictors. However, from the small magnitude of predictability, it is clear that predictors can only be noisy estimates of the true expected returns. In other words, the predictive regressions are subject to error-in-variables problem, which will bias estimates. To overcome the problem, Pastor and Stambaugh [31] proposed to model the expected return as an unobservable component and to allow its innovation being correlated with innovations in predictors. Specifically, they propose the following model:

$$r_{t+1} = \mu_t + \epsilon_{t+1} \quad (33)$$

$$\mu_{t+1} = \mu_0 + \phi\mu_t + u_{t+1} \quad (34)$$

$$z_{t+1} = \psi z_t + v_{t+1} \quad (35)$$

where μ_t is the expected return and z_t is the predictor. In this system, predictors affect the expected return

through a correlation between u_{t+1} and v_{t+1} . In other words, information in the predictors helps to improve the “quality” of the expected return estimates in the spirit of the classical SUR (seemingly unrelated) regression. Since the system of equations (33)–(35) can be reduced to a predictive regression when $\mu_t = z_t$, it should perform at least as good as the predictive regression. Additional constraints can be imposed to improve the estimation efficiency. For example, when there is a positive shock to the expected return, future expected returns will be high due to the persistence, which will result in a low price, or equivalently a low return. Therefore, we can incorporate this prior constraint of the negative correlation between u_{t+1} and ϵ_{t+1} . Using quarterly data and imposed economic prior in a Bayesian framework, Pastor and Stambaugh [31] found that the dividend yield is a very useful predictor.

In Pastor and Stambaugh [31], a predictor affects the expected return through an indirect channel by improving the precision of the expected return estimate as in the same spirit of the SUR regression. To push the idea further, Baranchuk and Xu [3] studied both the direct and indirect effects of predictors on the expected return. In particular, equations (34) and (35) are replaced by

$$\mu_{t+1} = \mu_0 + \phi\mu_t + \delta m_t + u_{t+1} \quad (36)$$

$$z_{t+1} = m_t + \eta_{t+1} \quad (37)$$

$$m_{t+1} = \alpha m_t + v_{t+1} \quad (38)$$

where m_t is the expected predictor. In this framework, the expected predictor directly affects the level of expected return, whereas the unexpected predictor continues to influence the efficiency of the time-varying expected return through its correlation with the innovation to the expected return. Using both the dividend yield and repurchasing yield, Baranchuk and Xu [3] were able to demonstrate the very different role played by the two predictors. The repurchasing yield affects the expected return directly, whereas dividend yield works through the indirect channel affecting the precision in the estimate of the expected return. From a technical perspective, such an elaborated model structure also avoids the potential spurious regression and possesses the ability to incorporate economic prior.

Out-of-sample Predictive Power

If predictability is due to time-varying expected returns, a representative investor will not attempt to make abnormal returns since both his/her risk exposure and risk tolerance change over time. However, a nonrepresentative (isolated) investor might be able to take the advantage of return predictability in order to outperform the market. Goyal and Welch [37] have run a horse racing on the out-of-sample predictive power for a model based on unconditional forecast *versus* models with conditional forecast using different predictors including the following:

- the dividend–price ratio and the dividend yield [10];
- the earnings price ratio and dividend–earnings (payout) ratio [26];
- the short-term interest rate [7];
- the term spread and the default spread [7, 16, 23];
- the inflation rate [14, 18];
- the book-to-market ratio [25, 32];
- the consumption, wealth, and income ratio [27]; and
- the aggregate net issuing activity [2].

After comparing the (conditional) root-mean-squared errors (RMSEs) with respect to the predicted returns to the (unconditional) RMSEs using a simple sample mean, Goyal and Welch [37] concluded that in-sample predictability can be very different from out-of-sample performance. In most cases, the unconditional RMSEs are smaller than the conditional RMSEs. Therefore, they believe that most results from predictive regressions are just statistical illusions.

Similar to the idea of using prior information to improve the predictive power for future returns as in [12], prior economic constraints are valuable information and should be used simultaneously. Campbell and Yogo [11] recognized that if we are really predicting the expected returns in a predictive regression, we should throw out the negative predicted returns since the expected returns should always be positive. By constraining the predicted returns to be nonnegative, Campbell and Yogo [11] found that most predictors in the above list are indeed useful in predicting future returns even out of sample.

In a related study, Xu [38] recognized that, given the low R^2 s in predictive regressions, it is very difficult to provide accurate prediction about the

magnitude of future returns due to errors in the parameter estimates. One has to at least estimate two parameters in a predictive regression, while a sample mean corresponds to only one parameter estimate. The additional estimation error could easily overwhelm the benefit of using predictors. Therefore, in out-of-sample studies, a more useful question to ask is whether we are able to predict the *direction* of future market movement. On the basis of this idea, Xu [38] had studied the economic significance of the following trading strategy:

Trading strategy: Invest in a risky asset today only if the predicted future asset return is positive.

Under the t -distributed return assumption, there exists a moderate condition, under which the trading strategy will outperform a buy-and-hold strategy. Using inflation, relative interest rate, and dividend–price ratio as predictors, Xu [38] had shown that such a trading strategy could potentially double the performance of a buy-and-hold strategy over the sample period from 1952 to 1998.

Concluding Comments

Given the vast literature on predictability, in this article attention was focused on the questions of the existence of predictability and the interpretation of predictability. Return predictability has always been a challenge to the EMH. The traditional view on the evidence is either denying the evidence with the help of statistical methods or attributing the phenomenon to market frictions. For example, most predictors, except for the past returns, are persistent. Such a statistical property may result in a spurious regression. Predictors are also imperfect, which will bring in an error-in-variables problem in estimation. Many market microstructure effects, such as bid–ask bounce and nonsynchronous trading, may induce autocorrelation in a short-run and among small stocks. The modern view, however, takes a more positive approach by recognizing the time-varying risk premium due to changes in either investment opportunities or investors' risk tolerance. If this is indeed the case, many variables that predict business cycles should also help to predict returns, for example, the interest rate. Other variables that contain a price component can also predict returns because prices reflect expectations and should summarize all future changes in the expected return or CF distributions.

Many statistical issues can be dealt with a more elaborated model structure and the use of economic prior. For example, if predictability is due to changes in the risk premium, we can model the expected returns explicitly as following an $AR(1)$ process and impose the nonnegativity constraint. We can also alleviate the market microstructure effects by using low-frequency returns such as monthly or quarterly returns. From an empirical perspective, however, we should not expect to find huge return predictability. It seems to be odd that some economic agents do not try to explore economic profits, even though they are not subject to the kind of risks that a representative investor might expose to. Indeed, many studies tend to find economically weak but statistically significant evidence of predictability.

Overall, we believe that the evidence points to the direction of predictable returns even under careful statistical inference. If this is the case, will evidence on predictability have any implications on asset pricing? The answer is yes as evident from the literature on testing the conditional asset pricing models. Predictability also has implications on investors' asset allocation decisions [22]. If returns are positively correlated over time, investors might want to allocate less wealth to equity. This is because a risk averse investor understands that he/she will be subject to even larger downside risk if today's return is low. This is still an active area of research.

End Notes

^aSuppose returns follow the following $AR(1)$ process,

$$r_t - \mu = \theta(r_{t-1} - \mu) + \epsilon_t$$

the true Sharpe ratio defined as μ/σ_ϵ can be expressed as

$$\frac{\mu}{\sigma_\epsilon} = \frac{1}{\sqrt{1 - \theta^2}} \frac{\mu}{\sigma_y}$$

^bWhen the discount rate is not zero, we can define a discounted process such that it is a martingale.

^cThe positive autocorrelation in the equal-weighted index shown in Table 1 is also consistent with the nonsynchronous trading story.

^dSince holdings in the future contracts are much smaller than the market capitalization of the 500 largest companies, the evidence could be consistent with our argument that the representative investors will not try to trade on the predictability, while nonrepresentative investor in a segment of the market could.

Real Options

Real options theory is about decision making and value creation in an uncertain world. It owes its success to its ability to reconcile frequently observed investment behaviors that are seemingly inconsistent with rational choices at the firm level. For instance, Dixit [15] uses real options to explain why firms undertake investments only if they expect a yield in excess of a required hurdle rate, thus violating the Marshallian theory of long- and short-run equilibria.^{a,b} This is because, relative to a setting in which there is no uncertainty, unforeseeable future payouts discourage commitment to a project unless the expected profitability of the project is sufficiently high. The real options methodology allows to identify and value risky investments and, under certain conditions, to even take advantage of uncertainty. Indeed, as we shall see, this valuation approach insures investments against possible adverse outcomes while retaining upside potential.^c

Definition of a Real Option

A real option gives its holder the right, but not the obligation, to take an action (e.g., deferring, expanding, contracting, or abandoning) for a specified price, called the *exercise—or strike—price*, on or before some specified future date. We can identify at least six factors that affect the value of a real option: the value of the underlying risky asset (i.e., the project, investment, or acquisition); the exercise price; the volatility of the value of the underlying asset; the time to expiration of the option; the interest rate; and the dividend rate of the underlying asset (i.e., the cash outflows or inflows over the life of the option). If the value of the underlying project, its standard deviation, or the time to expiration increase, so too does the value of the option. The value of the (call) option also increases if the risk-free rate of interest goes up. Lost dividends decrease the value of the option.^d A higher exercise price reduces (augments) the value of a call (put) option.^e

The quantitative origins of real options derive from the seminal work of Black and Scholes [2] and Merton [32] on financial options pricing (*see Black–Scholes Formula*). These roots are evident in the assumptions that trading and decision making

take place in continuous time and that the underlying sources of uncertainty follow Brownian motions. Even though these assumptions may be unsuitable in some corporate contexts, they permit to derive precise theoretical solutions, thereby proving to be essential.^{f,g} The focus of this earlier literature has been on valuing individual real options: the option to expand a project, for instance, is an American call option (*see American Options*). So is a deferral option that gives a firm the right to delay the start of a project. The option to abandon a project, or to scale back by selling a fraction of it for a fixed price, is formally an American put (*see American Options*). Real-world projects, however, are often more complex in that they involve a collection of real options, whose values may interact. The recent development in financial options interdependencies has enabled a smoother transition from a theoretical stage to an application stage.^h Margrabe's [29] valuation of an option to exchange one risky asset for another (*see Margrabe Formula*) finds immediate application in the modeling of switching options, which allow a firm to switch between two modes of operation. Geske [19] values options on options—called *compound options*—which may be applied to growth opportunities that become available only if earlier investments are undertaken. Phased investments belong to this category. Thus, almost paradoxically, in this relatively new field of research, the mathematically most complex models, which apply sophisticated contingent claims analysis techniques, entail a great wealth of factual applications.ⁱ Moreover, numerous studies show that real options represent a sizable fraction of a firm's value; both Kester [25] and Pindyck [35], for instance, estimate that the value of a firm's growth options is more than half its market value of equity if demand volatility exceeds 20%. For this reason, the theory of real options has gained significant importance among management practitioners whose choices determine the success or failure of their enterprises. Amram and Kulatilaka [1] collect several case studies to show practitioner audiences how real options can improve capital investment planning and results. In particular, they list three real options characteristics that are of great use to managers: (i) options payoffs are contingent on the manager's decisions; (ii) options valuations are aligned with financial market valuations; and (iii) options thinking can be used to design and manage strategic investments proactively. The real options paradigm,

however, is only the last stage in the evolution of valuation models. The traditional approach to valuing investment projects, which owes its origins to John Hicks and Irving Fisher, is based on net present value. This technique involves discounting expected net cash flows from a project at a discount rate that reflects the risk of those cash flows, called the *risk-adjusted* discount rate. Brennan and Trigeorgis [8] characterize this first-phase models as *static*, or *mechanistic*. The second-phase models are *control-able* cash-flow models, in which projects can be managed actively in response to the resolution of exogenous uncertainties. Since they ignore strategic investment, both first- and second-phase models often lead to suboptimal decisions. *Dynamic, game-theoretic* options models assume that projects can be managed actively, instead.^j These models take into account not only the resolution of exogenous uncertainties but also the actions of outside parties. For this reason, an area of immense importance within game-theoretic options models concerns market competition and strategy.

Strategic firm interactions are isomorphic to a portfolio of real options.^k Furthermore, the payouts of a project (as well as its value) can be seen as the outcome of a game among the inside agent, outside agents, and nature. Dixit [14] and Williams [40] were the first to consider real options within an equilibrium context. Smit and Ankum [37], among others, study competitive reactions within a game-theoretic framework under different market structures. In the same line of research is Grenadier's [21] analysis of a perfectly competitive real-estate market with stochastic demand and time to build.^l

Solution of the Basic Model

Besides particular cases, all investment expenditures have two important characteristics. First, they are at least partly irreversible, and second, they can be delayed so that the firm has the opportunity to wait for new information to arrive before committing any resources.

The most basic continuous-time model of irreversible investment was originally developed by McDonald and Siegel [31]. In their problem, a firm must decide when to invest in a single risky project, denoted by V , with a fixed known cost I . The project is assumed to follow a geometric Brownian motion

with expected return and volatility indicated by μ and σ , respectively. The project's payout rate equals δ . Formally, the process can be written as

$$\frac{dV}{V} = (\mu - \delta) dt + \sigma dz \quad (1)$$

where dz is the increment of a Wiener process and $(dz)^2 = dt$.^{m,n} In addition, denote the value of the firm's investment opportunity (its option to invest) by $F(V)$. It can be shown that the optimal rule is to invest at the date τ^* when the project's value first exceeds a certain optimal threshold V^* . This rule maximizes

$$F(V) = \max_{\tau} E[(V_{\tau} - I)e^{-\mu\tau}], \quad V_0 = V \quad (2)$$

over all possible stopping times τ , where E is the expectation operator. Prior to undertaking the project the only return to holding the investment option is its capital appreciation, so that

$$\mu F(V) dt = E[dF(V)] \quad (3)$$

Expanding $dF(V)$ using Itô's lemma yields

$$dF(V) = F'(V) dV + \frac{1}{2} F''(V) (dV)^2 \quad (4)$$

where primes indicate derivatives. Lastly, substituting equation (1) in (4) and taking expectations on both sides gives

$$\frac{1}{2} \sigma^2 V^2 F''(V) + (\mu - \delta) V F'(V) - \mu F(V) = 0 \quad (5)$$

Equation (5) must be solved simultaneously for the project value $F(V)$ and the optimal investment threshold V^* , subject to three boundary conditions:

$$F(0) = 0 \quad (6)$$

$$F(V^*) = V^* - I \quad (7)$$

$$F'(V^*) = 1 \quad (8)$$

Equation (6) is equivalent to stating that the investment option is worthless when the project's outcome is null. Equations (7) and (8) indicate the payoff and marginal value associated with the optimum. To derive V^* , we must guess a functional form

that satisfies equation (5) and verify if it works. In particular, if we take $F(V) = AV^\beta$, then

$$V^* = \frac{\beta I}{\beta - 1} \quad (9)$$

and

$$\beta = \frac{1}{2} - \frac{\mu - \delta}{\sigma^2} + \sqrt{\left(\frac{\mu - \delta}{\sigma^2} - \frac{1}{2}\right)^2 + \frac{2\mu}{\sigma^2}} \quad (10)$$

The optimal rule is to invest when the value of the project exceeds the cost by a factor $\frac{\beta}{\beta - 1} > 1$. This result is in contrast with net present value, which prescribes to invest as long as the value of the project exceeds the cost ($V^* = I$). However, since the latter rule does not account for uncertainty and irreversibility, it is incorrect and it leads to suboptimal decisions.

Furthermore, as it is apparent from the solution, the higher the risk of the project, measured by σ , the larger are the value of the option and the opportunity cost of investing. Increasing values of the growth rate, μ , also cause $F(V)$ and V^* to be higher. On the other hand, larger expected payout rates, δ , lower both $F(V)$ and V^* as holding the option becomes more expensive.

Dixit and Pindyck [16] show how the optimal investment rule can be found by using both dynamic programming (as it is done above) and contingent claims analysis.^o

Contingent claims methods require one important assumption: stochastic changes in the value of the project must be *spanned* by existing assets in the economy (see **Complete Markets**). Specifically, capital markets must be sufficiently *complete* so that one could find an asset, or construct a dynamic portfolio of assets, the price of which is perfectly correlated with the value of the project (see **Risk-neutral Pricing**).^{p,q} This assumption allows properly taking into account all the flexibility (options) that the project might have and using all the information contained in market prices (e.g., futures prices) when such prices exist.^r If the sources of uncertainty in a project are not traded assets (examples of which are product demand uncertainty, geological uncertainty, technological uncertainty, cost uncertainty, etc.), an equilibrium model of asset prices can be used to value the contingent claim.^s

Numerical Methods in Real Options

In practice, most real option problems must be solved using numerical methods. Until recently, these methods were so complex that only few companies found it practical to use them when formulating operating strategies. However, advances in both computational power and understanding of the techniques over the last 20 years have made it feasible to apply real options thinking to strategic decision making. Numerical solutions give not only the value of the project but also the optimal strategy for exercising the options.^t The simplest real option problems involving one or two state variables can be more conveniently solved using binomial or trinomial trees in one or two dimensions (see **Finite Element Methods**).^u When a problem involves more state variables, perhaps path dependent, the more practical solution is to use Monte Carlo simulation methods (see **Monte Carlo Simulation**).^{v,w} In order to do so, we use the assumption that properly anticipated prices (or cash flows) fluctuate randomly. Regardless of the pattern of cash flows that a project is expected to have, the changes in its present value will follow a random walk. This theorem, attributable to Paul Samuelson, allows us to combine any number of uncertainties by using Monte Carlo techniques, and to produce an estimate of the present value of a project conditional on the set of random variables drawn from their underlying distributions. More generally, there are two types of numerical techniques for option valuation: (i) those that approximate the underlying stochastic processes directly and (ii) those approximating the resulting partial differential equation. The first category includes lattice approaches and Monte Carlo simulations. Examples of the second category include numerical integration (see **Quadrature Methods**); and the implicit/explicit finite difference schemes (see **Finite Difference Methods for Barrier Options**; **Finite Difference Methods for Early Exercise Options**) used by Brennan [6], Brennan and Schwartz [7], and Majd and Pindyck [28], among others.

Conclusions

The application of option concepts to value real assets has been an important growth area in the theory and practice of finance. The insights and techniques

derived from option pricing have proven capable of quantifying the managerial operating flexibility and strategic interactions thus far ignored by conventional net present value and other quantitative approaches. This flexibility represents a substantial part of the value of many projects and neglecting it can undervalue investments and induce a misallocation of resources. By explicitly incorporating management flexibility into the analysis, real options have provided the tools for properly valuing corporate resources and capital budgeting.

End Notes

^aMarshall's [30] analysis states that if price exceeds long-run average cost, then existing firms expand and new ones enter a business.

^bSymmetrically, firms often do not exit a business for lengthy periods, even after the price falls substantially below long-run average cost. This phenomenon is dubbed *hysteresis*.

^cAmram and Kulatilaka [1], Brennan and Trigeorgis [8], Copeland and Antikarov [10], Dixit and Pindyck [16], Grenadier [21], Schwartz and Trigeorgis [36], and Smit and Trigeorgis [38] represent core reference volumes on real investment decisions under uncertainty. The survey article by Boyer *et al.* [4] is a noteworthy collection of all most notable contributions to the literature on strategic investment games, from the pioneering works of Gilbert and Harris [20] and Fudenberg and Tirole [18] to more recent contributions.

^dFor a thorough examination of the variables driving real options' analysis, the reader is referred to [10], Chapter 1.

^eAn interesting example on the effect of an option's exercise price on its value is presented by Moel and Tufano [33]. They study the bidding for rights to explore and develop a copper mine in Peru. A peculiar aspect of the transaction is the nature of the bidding rules that bidders were required to follow by the Peruvian government. Each bid was required to specify the minimum amount that the bidder would spend on developing the property if they decided to go ahead after exploration. This is equivalent to allowing the bidders to specify the exercise price of their development option. This structure gave rise to incentives that affected the amount that firms would offer, thus inducing successful bidders to make uneconomic investments.

^fBoyarchenko and Levendorskii [3] relax these assumptions and show how to analyze firm decisions in discrete time.

^gCox, Ross, and Rubinstein's [12] binomial approach enables a more simplified valuation of options in discrete time.

^hDetemple [13] provides a complete treatment of American-style derivatives pricing. He analyzes in detail

both plain and exotic contingent claims and presents recent results on the numerical computation of optimal exercise boundaries, hedging prices, and hedging portfolios.

ⁱFlexible manufacturing, natural resource investments, land development, leasing, large-scale energy projects, research and development, and foreign investment are all examples of real options cases.

^jTrigeorgis and Mason [39] remark that option valuation can be seen as a special version of decision tree analysis. Decision scientists propose the use of decision tree analysis [34] to capture the value of operating flexibility associated with many projects.

^kLuerhman [27] explains how a business strategy compares to a series of options more than to a single option. *De facto*, executing a strategy almost always involves making a sequence of decisions: some actions are taken immediately, while others are deliberately deferred.

^lThe time-to-build and continuous-time features of Grenadier's [21] model translate into an infinite state space. Despite this, he is able to determine the optimal construction rules by engineering an artificial economy with a finite state space in which the equilibrium strategy is identical to that of the true economy.

^mAccording to equation (1), the current project value is known but its future values are uncertain.

ⁿChapters 3 and 4 in [16] provide a thorough overview of the mathematical tools necessary to study investment decision using a continuous-time approach.

^oAlthough equivalent, the two methodologies are conceptually rather different: while the former lies on the option's value satisfying the Bellman equation, the latter is founded on the construction of a risk-free portfolio formed by a long position in the firm's option and a short position in units of the firm's project. Chapter 5 in [16] presents a detailed explanation, along with a guided derivation, of the optimal rule obtained on adopting each technique.

^pDuffie [17] gives great emphasis to the implications of complete markets for asset pricing under uncertainty.

^qHarrison and Kreps [22], Harrison and Pliska [23], and others have shown that, in complete markets, the absence of arbitrage implies the existence of a probability distribution such that securities are priced on the basis of their discounted (at the risk-free rate) expected cash flows, where expectation is determined under the *risk-neutral probability measure*. If all risks can be hedged, this probability is unique. The critical advantage of working in the risk-neutral environment is that it is a convenient environment for option pricing.

^rThe reader is referred to [36] for a more rigorous discussion on the application of contingent claims analysis to determine a project's optimal operating policy.

^sSee [11] for the derivation of a fundamental partial differential equation that must be satisfied by the value of all contingent claims on the value of state variables that are not traded assets.

[†]Broadie and Detemple [9] conduct a careful evaluation of the many methods for computing American option prices.

^uBoyle [5] shows how lattice frameworks can be extended to handle two state variables.

^vIn the last few years, methods have been developed, which allow using simulations for solving American-style options. For example, Longstaff and Schwartz [26] developed a least-squares Monte Carlo approach to compare the value of immediate exercise with the conditional expected value from continuation.

^wHull and White [24] suggest a control variate technique to improve computational efficiency when a similar derivative asset with an analytic solution is available.

Employee Stock Options

Employee stock options (ESOs) are call options issued by a company and given to its employees as part of their remuneration. The rationale is that granting the employee options will align his or her interests with those of the firm's shareholders. This is particularly relevant for managers and Chief Executive Officers (CEOs) whose behavior has more impact on firm value than that of lower ranked employees.

ESOs are prevalent in both the United States and Europe. In the fiscal year 1999, 94% of the S&P 500 companies granted options to their top executives, and the value at the grant date represented 47% of total pay for the CEOs [14]. The 2005 Mercer Compensation Survey [34] reports that over 75% of CEOs receive option grants and options account for 32% of CEO pay. The Hay Group's 2006 European Executive Pay Survey [15] found that 55% of the companies in the study used stock options.

ESOs are American call options on the company stock granted to the employee. They typically have a number of characteristics that distinguish them from financial options; see [38] and [35] for overviews. There is usually an initial *vesting* period during which the options cannot be exercised. Cliff vesting is a structure where all options granted on a given date become exercisable after an initial period, usually 2–4 years. Stepped vesting refers to a structure where a proportion of an option grant becomes exercisable each year, for example, 10% after one year, then 20%, 30%, and 40% each subsequent year. The most common structure is straight vesting where the proportions are equal, say one-third of the grant is exercisable after each of the first three years (see [2, 30], and [25]). During this period, typically, the employee must forfeit the remaining unvested options if he or she resigned or is fired. Clearly, if there is no vesting period, the options are American style, whereas, in the limit, as the vesting period approaches maturity, the options become European (see **American Options; Call Options** for descriptions of European and American options).

After the vesting period, the options may be exercised at any time up to and including the maturity date. These options are typically long dated with a 10-year maturity being most common. The employee

is not able to sell or transfer the options at any time. This is in keeping with the alignment or incentive effect of options. The option terms are modified if the employee exits the firm either because he or she is fired, leaves, retires, or dies. These “sunset rules” vary widely across firms (see [8] for details), but typically the employee is given a period of time in which to exercise the options or forfeit them. The length of time is generally longest if the employee retires and shortest if the employee leaves or is fired. In addition to being unable to unwind an option position by selling it, employees are typically also restricted from short selling the stock of their company and thus are very restricted in terms of hedging their option exposure [5].

There have been a number of empirical studies of ESO exercise patterns. Huddart and Lang [23] study exercise behavior in a sample of eight firms that volunteered internal records on option grants and exercises from 1982 to 1994. They find a pervasive pattern of option exercises well before expiration—the mean fraction of option life elapsed at the time of exercise varied from 0.26 to 0.79 over companies. Bettis *et al.* [2] analyze a unique database of more than 140 000 option exercises by corporate executives at almost 4000 firms during the period 1996 through 2002. They find 10-year options were exercised a median of 4.25 years before expiry. A further feature documented in the data is that of block exercise. Huddart and Lang [23] find that the mean fraction of options from a single grant exercised by an employee at one time varied from 0.18 to 0.72 over employees at a number of companies. Similarly, Aboody [1] reports yearly mean percentages of options exercised over the life of 5 and 10 year options, showing exercises are spread over the life of the options. Some of these block exercises are due to the nature of the vesting structure—for instance, Huddart and Lang [23] find spikes on vest dates corresponding to large exercises on those dates—but there are also other block exercises on dates that cannot be explained by vesting.

There are many questions of interest—including “What is the employee's optimal exercise policy?”, “What are the options worth to him or her?”, “What is the corresponding cost to the company of granting the options?” The employee's exercise policy and option value should incorporate the features described above—his or her inability to hedge being key. The cost to the company should reflect the

value of the option liability to the issuing corporation. This usually entails the assumption that shareholders are well diversified, so the cost should be the risk-neutral option value conditional on the optimal exercise behavior of the employee. This distinction between the option value to the employee (often called *subjective value*) and the cost to the company is important and arises because the employee cannot perfectly hedge the risk of the option exposure, while shareholders are typically assumed to be well diversified.

The need to quantify the company cost is particularly relevant in light of changes in accounting rules, which require companies to expense options at the grant date. In 1995, the Financial Accounting Standards Board (FASB) set a standard to require firms to expense stock options using “fair value”. However, this included the possibility to calculate the option cost to the firm as the option’s intrinsic value at the grant date. Perhaps motivated by this, companies mainly granted options that were at-the-money thus calculating a zero value for the expense. The huge growth of employee options and a series of corporate scandals led to pressure for changes to these rules, and new regulations (FASB 123R in the United States, International Financial Reporting Standards (IFRS) 2 in Europe) were introduced in 2004. From 2005 onward, these regulations required companies to use a “fair value method” of accounting for the expense of employee options, and although recommendations are made concerning appropriate methods, there is still much scope for interpretation by companies. For instance, use of the (European) Black–Scholes price with an estimated “expected term” is an acceptable and popular approach. Despite these changes, the granting of options that are at-the-money is still typical.

To take into account the nonhedgability aspect of employee options, we need to move outside of the complete market or risk-neutral pricing framework to an incomplete setting (see **Complete Markets**). There have been many papers in the literature in this direction, beginning with [22, 31, 32], and [14], amongst others. These papers typically develop binomial models that take trading restrictions and employee risk aversion into account and compute a certainty equivalent or subjective value for the employee options. These models make the simplistic assumption that any nonoption wealth is invested in a riskless bank account, and most treat the options as

European. Also in a binomial model, Cai and Vijn [3] and Carpenter [5] assume nonoption or outside wealth is invested in a Merton-style portfolio, but only allow for a one-off choice of this portfolio.

Many of the papers mentioned above observe that the utility-based or subjective valuation to the employee is much lower than the equivalent Black–Scholes value (the value obtained in an equivalent complete market setting); however, this is not universally true in models where nonoption wealth is invested in a riskless bond [14]. Generally, however, the (subjective) value of the options to the employee is less than the cost of the options to the company because of the employee’s hedging restrictions.

These models have been extended to incorporate the impact of optimal investment of outside wealth in a market or risky asset, rather than just a bank account. This was tackled in the natural setting of utility-indifference pricing (see [19] for a survey containing many references) for European options by Henderson [17]. This allows the employee to reduce risk by partial hedging in the market asset, which would seem to reflect what can be done in practice. The basic setup for continuous-time models with hedging in the market asset is as follows. The market M follows a geometric Brownian motion

$$dM/M = \mu dt + \sigma dB \quad (1)$$

where μ, σ are constants, and B is standard Brownian motion. Let W be a standard Brownian motion and assume $dBdW = \rho dt$. We can write $dW = \rho dB + \sqrt{1 - \rho^2}dZ$ for Z a Brownian motion independent of B . The company stock S also follows a geometric Brownian motion:

$$\begin{aligned} dS/S &= \nu dt + \eta dW \\ &= \nu dt + \eta(\rho dB + \sqrt{1 - \rho^2}dZ) \end{aligned} \quad (2)$$

The term $\rho^2\eta^2$ represents the hedgable or market component of the total risk of the stock and $(1 - \rho^2)\eta^2$ is the unhedgable or idiosyncratic/firm-specific risk of the stock. When $\rho^2 = 1$ all the risk can be hedged and an employee with an option on the stock S is able to perfectly hedge the risk he or she faces. (To avoid arbitrage, we should have $\nu - r = (\mu - r)\eta/\sigma$. More generally, CAPM imposes the relation

$v - r = (\mu - r)\eta\rho/\sigma$; see **Capital Asset Pricing Model**).

The employee can invest in a riskless asset with interest rate r and hold a cash amount θ_t in the market at time t . The dynamics of the wealth account X are then

$$dX = \theta dM/M + r(X - \theta)dt \quad (3)$$

If the employee is granted λ European call options with strike K then he or she solves

$$V(t, X_t, S_t, \lambda) = \sup_{\theta_t: \theta_t \geq t} E_t[U(X_T + \lambda(S_T - K)^+)] \quad (4)$$

Under the assumption of exponential utility, closed-form solutions are obtained for the value function. The utility-based or utility-indifference value p of the λ options solves $V(t, x + p, S_t, 0) = V(t, x, S_t, \lambda)$. In such models, it is straightforward to show that, in the limit, as the (absolute value of) correlation between the company stock and market approaches one, the Black–Scholes or complete market value is recovered. This value is then an upper bound on the utility-based valuation. In a European option setting, the Black–Scholes value represents the cost to the company, so we see the value to the employee is lower than the cost to the company. The other comparison of interest is to consider what difference the ability to undertake partial hedging in the market makes. The ability to partially hedge is valuable to the employee and his or her utility-based or subjective option value is higher than without the hedging/investment opportunity. In other words, the subjective value increases in (absolute value of) correlation. Similar to the models without the market asset, the higher the employee's risk aversion, the lower the utility-based option value.

Of course, as we described earlier, employee stock options are American options, and allow for early exercise once the options have vested. Some of the aforementioned papers also treat American style options and the general intuition is that hedging restrictions of the employee result in an earlier exercise and a lower subjective value than the equivalent Black–Scholes (complete market) American option. In the continuous-time model with investment in the market asset, closed-form results are found under the assumptions of exponential utility and perpetual options in [18] and numerical solutions for finite maturity in [33]. Kadam *et al.* [29]

considered the case of the perpetual option but without the partial hedging in the market. The exercise threshold and option values both decrease with risk aversion and increase with (absolute value of) correlation. Just as in the European case, the ability to partially hedge risk is valuable to the employee. He or she places a higher value on the option and waits longer to exercise it. It is also possible that stock volatility reduces the option value in some scenarios because of the interaction of the convex payoff with the concave utility function; see [17, 18, 33], and also [37]. Since the cost to the company is just the risk-neutral option value conditional on optimal exercise by the employee, it is also decreasing with risk aversion and increasing with (absolute value of) correlation [13]. Detemple and Sundaresan [9] and Ingersoll [25] also allow for optimal investment in a market portfolio and consider numerical approaches to the marginal pricing of small quantities of options.

As mentioned earlier, the data indicates that employees exercise options in a number of tranches on different occasions. Consideration of models that only allow for one option or one exercise time is not consistent with this observation. Vesting is one feature that clearly encourages such block exercise behavior, and indeed, Huddart and Lang [23] observe that many exercises take place immediately when the options vest. However, vesting does not appear to explain all of the intertemporal exercises, since not all exercises occur immediately upon vesting. Another reason for intertemporal exercise is risk aversion and the inability to hedge risk due to restrictions. Jain and Subrahmanian [26] consider a binomial model for a risk-averse employee who is granted a number of options. Grasselli [12] extends the binomial framework to include optimal investment in a correlated market asset. These papers find numerically that optimal behavior is to exercise options when the stock price reaches a boundary and the discrete nature of the model results in exercise occurring at a discrete set of dates or stock price levels. Rogers and Scheinkman [36] make similar observations numerically in a discrete approximation to a continuous-time model without investment opportunities in a market asset.

Grasselli and Henderson [13] show that under the assumption of exponential utility and perpetual options, closed-form solutions can be derived for the multiple-option problem with investment opportunities in a market asset. In fact, they show that

given N options, there are N unique stock price thresholds at which the employee should exercise an option. These thresholds are obtained using a recursive relation. The price thresholds are increasing as the quantity of options falls. In other words, when the employee has fewer options remaining, he or she is exposed to less risk, and thus is willing to wait for a higher price threshold before exercising further options. Similar comparative statics apply as in the single American option case—thresholds, option values, and company cost are decreasing in risk aversion and increasing in (absolute value of) correlation. In addition, they show that the cost to the company is underestimated if a single optimal exercise threshold is used. Since, in reality, options are not exercised one at a time, the paper also introduces a transaction cost on exercise, which restores block exercise as the optimal solution, again found in closed form. Leung and Sircar [33] consider the finite-maturity version of the problem, which leads to numerical solution of the free-boundary problem. They also include features such as vesting and job termination risk.

As described earlier, option terms change upon departure of an employee from the company and this should be incorporated into pricing models. Employee departure is typically modeled by an exogenous exponentially distributed time with constant intensity, independent of the stock price, similar to a reduced-form approach in credit modeling. (*see Structural Default Risk Models*). The papers [5, 6, 27, 39], and [33], among others, incorporate departure into a variety of setups in this manner.

Although we do not discuss estimation in any detail here, it is clear that estimation of such models is difficult. The models require estimates of risk aversion, outside wealth, and employee departure rate, which are not easily obtained. Bettis *et al.* [2] and Carpenter [5] have attempted calibration exercises on utility style models to exercise data; however, many simplifying assumptions have to be made due to data limitations. For example, they assume an option grant is exercised on one date only rather than on multiple occasions. Perhaps surprising is the finding of Carpenter [5] that after a calibration to data, a reduced-form model of employee departure is as capable as a utility-maximizing model in explaining option exercises. This finding motivates another strand of the literature, which models option exercise exogenously by postulating an exercise boundary in terms of the moneyiness of the

option; see [24] and [7]. This style of model has the attraction of simplicity and is much easier for calibration since the employee's risk aversion is no longer used. For this reason, it may well be a fruitful approach for calculating an approximation to the cost of the options to the company for accounting purposes.

We now turn to briefly discuss a number of other features relevant in employee compensation. Typically employees receive new grants of options periodically; however, companies also engage in resetting (where the option strike of existing options is adjusted downward when the options are out-of-the-money) and reloading (where additional options are granted automatically when existing options are exercised [10]).

Besides the traditional employee options described in this article, companies have increasingly granted performance-based options, which link option vesting or exercise to the achievement of market or accounting-based performance targets. These options are very popular in Europe, but have, until recently, been less common in the United States; see [11] and references therein. Compensation linked to accounting data is potentially open to manipulation and managers with such options may be motivated to inflate earnings. There is a large literature on the connection between compensation involving accounting-based targets and earnings management, either of a direct nature [4]) or accrual-based management or manipulation Healy [16].

Performance-based options can also have exercise prices contingent on performance relative to a comparison group—these are known as indexed options; see Johnson and Tian [28] who value such options in a risk-neutral framework using techniques from exchange or Margrabe options (*see Margrabe Formula*). Managers are then rewarded as a function of relative performance relative to a peer group rather than on absolute performance [20].

Other important issues that have not been discussed here include the impact of dilution—when options are exercised, the company typically issues new shares. Another important issue is the influence the CEO has on the stock price *via* his or her effort or choice of projects/risk. The problem of how best to compensate managers, given the benefits of improved incentives and the costs of inefficient risk-sharing, is the subject of a large literature on the principal agent problem; see the classic reference [21].

Arbitrage Strategy

It is difficult to imagine a normative condition that is more widely accepted and unquestionable in the minds of anyone involved in the field of quantitative finance other than the *absence of arbitrage opportunities* in a financial market. Put plainly, an *arbitrage strategy* allows a financial agent to make certain profit out of nothing, that is, out of zero initial investment. This has to be disallowed on economic basis if the market is in equilibrium state, as opportunities for riskless profit would result in an instantaneous movement of prices of certain financial instruments.

Let us give an illustrative example of an arbitrage strategy in the foreign exchange market, commonly called the *triangular arbitrage*. Suppose that Mary, in Paris, is buying^a the US dollar for €0.685. Tom, in San Francisco, is buying Japanese yen for \$0.009419. Finally, Toru, in Tokyo, is buying one euro for ¥155.02. All these transactions are supposed to be able to occur at the *same time*. There is something worth noting in the situation just described—something that could allow you to make riskless profit. Let us see how. You borrow \$10 000 from your rich aunt Clara and tell her you will return the money in a matter of minutes. First, you approach Mary and change all your dollars to euros. This means that you will get €6850. With the euros in hand, you contact Toru and change them into yen—you will get $¥(6850 \times 155.02) = ¥1\,061\,887$. Finally, you call Tom, wire him all your yen and change them back to dollars, which gets you $\$(1\,061\,887 \times 0.009419) \equiv \$10\,001.91$. You give the \$10 000 back to your aunt Clara as promised, and you have managed to create \$1.91 out of thin air.

Although the above-mentioned example is oversimplistic, it gives a clear idea of what arbitrage is: a position on a combination of assets that requires zero initial capital and results in a profit with *no* risk involved. Let us now take a step further and see what will happen under the situation of the preceding example. As more and more investors become aware of the discrepancy between prices, they will all try to use the same smart strategy that you used for their benefit. Everyone will be trying to exchange US dollars for euros in the first step of the arbitrage, which will drive Mary to start buying the US dollar for less than €0.685 because of the high demand for the euros she is selling. Similarly, Tom will start buying

Japanese yen for less than \$0.009419 and Toru will be buying euro for less than ¥155.02. Very soon, the situation will be such that nobody is able to make a riskless profit anymore.

The economic rationale behind asking for nonexistence of arbitrage opportunities is based exactly on the discussion in the previous paragraph. If arbitrage opportunities were present in the market, a multitude of investors would try to take advantage of them simultaneously. Therefore, there would be an almost instantaneous move of the prices of certain financial instruments as a response to a supply–demand imbalance. This price movement will continue until any opportunity for riskless profit is no longer available.

It is important to note that the preceding, somewhat theoretical, discussion does *not* imply that arbitrage opportunities *never* exist in practice. On the contrary, it has been observed that opportunities for some, albeit usually minuscule, riskless profit appear frequently as a consequence of the huge amount of distant geographic trading locations, as well as a result of the numerous financial products that have sprung up and are sometimes interrelated in complicated ways. Realizing that such opportunities exist is a matter of rapid access to information that a certain group of investors, so-called *arbitrageurs*, has. It is rather the *existence* of arbitrageurs acting in financial markets that ensures that when arbitrage opportunities exist, they will be fleeting.

The principle of not allowing for arbitrage opportunities in financial markets has far-reaching consequences and has immensely boosted research in quantitative finance. The ground-breaking papers of Black (*see* **Black, Fischer**) and Scholes [1] and Merton (*see* **Merton, Robert C.**) [3], published in 1973, were the first instances explaining how absence of arbitrage opportunities leads to rational pricing and hedging formulas for European-style options in a geometric Brownian motion financial model.^b This idea was consequently taken up and generalized by many authors and has led to a profound understanding of the interplay between the economics of financial markets and the mathematics of stochastic processes, with deep-reaching results—*see* **Fundamental Theorem of Asset Pricing; Risk-neutral Pricing; Equivalent Martingale Measures; and Free Lunch** for some amazing developments on this path.

We close the discussion of arbitrages on an amusing note. Such is the firm belief on the principle of not allowing for arbitrage opportunities in financial modeling that even jokes have been created in order to substantiate it further. We quote directly from Chapter 1 of [2], which can be used as an excellent introduction to arbitrage theory: *A professor working in Mathematical Finance and a normal^c person go on a walk and the normal person sees a €100 bill lying on the street. When the normal person wants to pick it up, the professor says: “Don’t try to do that. It is absolutely impossible that there is a €100 bill lying on the street. Indeed, if it were lying on the street, somebody else would have picked it up before you.”*

End Notes

^a. All the prices referred to in this example are *bid* prices of the currencies involved.

^b. For historical perspectives regarding option pricing and hedging, see **Black, Fischer; Merton, Robert C.; Arbitrage: Historical Perspectives; and Option Pricing Theory: Historical Perspectives**. For a more thorough quantitative treatment, see **Risk-neutral Pricing**.

^c. Is this bold distancing from normality of mathematical finance professors, clearly implied from the authors of [2], a decisive step toward illuminating the perception they have of their own personalities? Or is it just a gimmick used to add another humorous ingredient to the joke? The answer is left for the reader to determine.

Fundamental Theorem of Asset Pricing

Consider a financial market modeled by a price process S on an underlying probability space $(\Omega, \mathcal{F}, \mathbb{P})$. The *fundamental theorem of asset pricing*, which is one of the pillars supporting the modern theory of Mathematical Finance, states that the following two statements are *essentially* equivalent:

1. S does not allow for arbitrage (NA).
2. There exists a probability measure Q on the underlying probability space $(\Omega, \mathcal{F}, \mathbb{P})$, which is equivalent to $\mathbb{P}$ and under which the process is a martingale.

We have formulated this theorem in vague terms, which will be made precise in the sequel: we formulate versions of this theorem that use precise definitions and avoid the use of the word *essentially*.

The story of this theorem started—like most of modern Mathematical Finance—with the work of Black (see **Black, Fischer**), Scholes [3], and Merton (see **Merton, Robert C.**) [25]. These authors consider a model $S = (S_t)_{0 \leq t \leq T}$ of geometric Brownian motion proposed by Samuelson (see **Samuelson, Paul A.**) [30], which is widely known today as the Black–Scholes model. Presumably every reader of this article is familiar with the well-known technique to price options in this framework (see **Risk-neutral Pricing**): one changes the underlying measure $\mathbb{P}$ to an equivalent measure Q under which the discounted stock price process is a martingale. Subsequently, one prices options (and other derivatives) by simply taking expectations with respect to this “risk neutral” or “martingale” measure Q .

In fact, this technique was *not* the novel feature of [3, 25]. It was used by actuaries for some centuries and it was also used by Bachelier [2] in 1900 who considered Brownian motion (which, of course, is a martingale) as a model $S = (S_t)_{0 \leq t \leq T}$ of a stock price process. In fact, the prices obtained by Bachelier (see **Bachelier, Louis (1870–1946)**) by this method were—at least for the empirical data considered by Bachelier himself—very close to those derived from the celebrated Black–Merton–Scholes formula ([34]).

The decisive *novel feature* of the Black–Merton–Scholes approach was the argument that links this pricing technique with the notion of arbitrage: the payoff function of an option can be precisely *replicated* by trading dynamically in the underlying stock. This idea, which is credited in footnote 3 of [3] to Merton, opened a completely new perspective on how to deal with options, as it linked the pricing issue with the idea of hedging, that is, dynamically trading in the underlying asset.

The technique of replicating an option is completely absent in Bachelier’s early work; apparently, the idea of “spanning” a market by forming linear combinations of primitive assets first appears in the Economics literature in the classic paper by Arrow (see **Arrow, Kenneth**) [1]. The mathematically delightful situation, that the market is complete in the sense that all derivatives can be replicated, occurs in the Black–Scholes model as well as in Bachelier’s original model of Brownian motion (see **Second Fundamental Theorem of Asset Pricing**). Another example of a model in continuous time sharing this property is the compensated Poisson process, as observed by Cox and Ross (see **Ross, Stephen**) [4]. Roughly speaking, these are the only models in continuous time sharing this seductively beautiful “martingale representation property” (see [16, 39] for a precise statement on the uniqueness of these families of models).

Appealing as it might be, the consideration of “complete markets” as above is somewhat dangerous from an economic point of view: the precise replicability of options, which is a sound mathematical theorem in the framework of the above models, may lead to the illusion that this is also true in economic reality. However, these models are far from matching reality in a one-to-one manner. Rather they only highlight important aspects of reality and therefore should not be considered as ubiquitously appropriate.

For many purposes, it is of crucial importance to put oneself into a more general modeling framework.

When the merits as well as the limitations of the Black–Merton–Scholes approach unfolded in the late 1970s, the investigations on the fundamental theorem of asset pricing started. As Harrison and Pliska formulate it in their classic paper [15]: “it was a desire to better understand their formula which originally motivated our study, ...”.

The challenge was to obtain a deeper insight into the relation of the following two aspects: on

one hand, the methodology of pricing by taking expectations with respect to a properly chosen “risk neutral” or “martingale” measure Q ; on the other hand, the methodology of pricing by “no arbitrage” considerations. Why, after all, do these two seemingly unrelated approaches yield identical results in the Black–Merton–Scholes approach? Maybe even more importantly: how far can this phenomenon be extended to more involved models?

To the best of the author’s knowledge, the first person to take up these questions in a systematic way was Ross (*see* **Ross, Stephen**) [29]; see also [4, 27, 28]. He chose the following setting to formalize the situation: fix a topological, ordered vector space (X, τ) , modeling the possible cash flows (e.g., the payoff function of an option) at a fixed time horizon T . A good choice is, for example, $X = L^p(\Omega, \mathcal{F}, \mathbb{P})$, where $1 \leq p \leq \infty$ and $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$ is the underlying filtered probability space. The set of marketed assets M is a subspace of X .

In the context of a stock price process $S = (S_t)_{0 \leq t \leq T}$ as above, one might think of M as all the outcomes of an initial investment $x \in \mathbb{R}$ plus the result of subsequent trading according to a predictable trading strategy $H = (H_t)_{0 \leq t \leq T}$. This yields (in discounted terms) an element

$$m = x + \int_0^T H_t dS_t \quad (1)$$

in the set M of marketed claims. It is natural to price the above claim m by setting $\pi(m) = x$, as this is the net investment necessary to finance the above claim m .

For notational convenience, we shall assume in the sequel that S is a one-dimensional process. It is straightforward to generalize to the case of d risky assets by assuming that S is $\mathbb{R}^d$ -valued and replacing the above integral by

$$m = x + \int_0^T \sum_{i=1}^d H_t^i dS_t^i \quad (2)$$

Some words of warning about the stochastic integral (1) seem necessary. The precise admissibility conditions, which should be imposed on the stochastic integral (1), in order to make sense both mathematically as well as economically, are a subtle issue. Much of the early literature on the fundamental theorem of asset pricing struggled exactly with this

question. An excellent reference is [14]. Ross [29] circumvented this problem by deliberately leaving this issue aside and simply starting with the modeling assumption that the subset $M \subseteq X$ as well as a pricing operator $\pi : M \rightarrow \mathbb{R}$ are *given*.

Let us now formalize the notion of arbitrage. In the above setting, we say that the **no arbitrage** assumption is satisfied if, for $m \in M$, satisfying $m \geq 0$, $\mathbb{P}$ -a.s. and $\mathbb{P}[m > 0] > 0$, we have $\pi(m) > 0$. In prose, this means that it is not possible to find a claim $m \in M$, which bears no risk (as $m \geq 0$, $\mathbb{P}$ -a.s.), yields some gain with strictly positive probability (as $\mathbb{P}[m > 0] > 0$), and such that its price $\pi(m)$ is less than or equal to zero.

The question that now arises is whether it is possible to extend $\pi : M \rightarrow \mathbb{R}$ to a nonnegative, continuous linear functional $\pi^* : X \rightarrow \mathbb{R}$.

What does this have to do with the issue of martingale measures? This theme was developed in detail by Harrison and Kreps [14]. Suppose that $X = L^p(\Omega, \mathcal{F}, \mathbb{P})$ for some $1 \leq p < \infty$, that the price process $S = (S_t)_{0 \leq t \leq T}$ satisfies $S_t \in X$, for each $0 \leq t \leq T$, and that M contains (at least) the “simple integrals” on the process $S = (S_t)_{0 \leq t \leq T}$ of the form

$$m = x + \sum_{i=1}^n H_i (S_{t_i} - S_{t_{i-1}}) \quad (3)$$

Here $x \in \mathbb{R}$, $0 = t_0 < t_1 < \dots < t_n = T$ and $(H_i)_{i=1}^n$ is a (say) bounded process which is *predictable*, that is, H_i is $\mathcal{F}_{t_{i-1}}$ -measurable. The sums in equation (3) are the Riemann sums corresponding to the stochastic integrals (1). The Riemann sums (3) have a clear-cut economic interpretation [14]. In equation (3) we do not have to bother about subtle convergence issues as only finite sums are involved in the definition. It is therefore a traditional (minimal) requirement that the Riemann sums of the form (3) are in the space M of marketed claims; naturally, the price of a claim m of the form (3) should be defined as $\pi(m) = x$.

Now suppose that the functional π , which is defined for the claims of the form (3) can be extended to a continuous, nonnegative functional π^* defined on $X = L^p(\Omega, \mathcal{F}, \mathbb{P})$. If such an extension π^* exists, it is induced by some function $g \in L^q(\Omega, \mathcal{F}, \mathbb{P})$, where $\frac{1}{p} + \frac{1}{q} = 1$. The nonnegativity of π^* is tantamount to $g \geq 0$, $\mathbb{P}$ -a.s., and the fact that $\pi^*(1) = 1$ shows that g is the density of a probability measure Q with Radon–Nikodym derivative $\frac{dQ}{d\mathbb{P}} = g$.

If we can find such an extension π^* of π , we thus find a probability measure Q on $(\Omega, \mathcal{F}, \mathbb{P})$ for which

$$\pi^* \left(\sum_{i=1}^n H_i (S_{t_i} - S_{t_{i-1}}) \right) = \mathbb{E}_Q \left[\sum_{i=1}^n H_i (S_{t_i} - S_{t_{i-1}}) \right] \quad (4)$$

for every bounded predictable process $H = (H_i)_{i=1}^n$ as above, which is tantamount to $(S_t)_{0 \leq t \leq T}$ being a martingale (see [Th. 2] [14], or [Lemma 2.2.6] [11]).

To sum up, in the case $1 \leq p < \infty$, finding a continuous, nonnegative extension $\pi^* : L^p(\Omega, \mathcal{F}, \mathbb{P}) \rightarrow \mathbb{R}$ of π amounts to finding a $\mathbb{P}$ -absolutely continuous measure Q with $\frac{dQ}{d\mathbb{P}} \in L^q$ and such that $(S_t)_{0 \leq t \leq T}$ is a martingale under Q .

At this stage, it becomes clear that in order to find such an extension π^* of π , the Hahn–Banach theorem should come into play in some form, for example, in one of the versions of the separating hyperplane theorem.

In order to be able to do so, Ross assumes ([p. 472] [29]) that “...we will endow X with a strong enough topology to insure that the positive orthant $\{x \in X | x > 0\}$ is an open set, ...”. In practice, the only infinite-dimensional ordered topological vector space X , such that the positive orthant has nonempty interior, is $X = L^\infty(\Omega, \mathcal{F}, \mathbb{P})$, endowed with the topology induced by $\|\cdot\|_\infty$.

Hence the two important cases, applying to Ross’ hypothesis, are when either the probability space Ω is finite, so that $X = L^p(\Omega, \mathcal{F}, \mathbb{P})$ simply is finite dimensional and its topology does not depend on $1 \leq p \leq \infty$, or if $(\Omega, \mathcal{F}, \mathbb{P})$ is infinite and $X = L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ equipped with the norm $\|\cdot\|_\infty$.

After these preparations we can identify the two convex sets to be separated: let $A = \{m \in M : \pi(m) \leq 0\}$ and B be the interior of the positive cone of X . Now make the easy, but crucial, observation: these sets are disjoint if and only if the no-arbitrage condition is satisfied. As one always can separate an open convex set from a disjoint convex set, we find a functional $\tilde{\pi}$, which is strictly positive on B , while $\tilde{\pi}$ takes nonpositive values on A . By normalizing $\tilde{\pi}$, that is, letting $\pi^* = \tilde{\pi}(1)^{-1} \tilde{\pi}$ we have thus found the desired extension.

In summary, the first precise version of the fundamental theorem of asset pricing is established in [29], the proof relying on the Hahn–Banach theorem. There are, however, serious limitations: in the case of

infinite $(\Omega, \mathcal{F}, \mathbb{P})$, the present result only applies to $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ endowed with the norm topology. In this case, the continuous linear functional π^* only is in $L^\infty(\Omega, \mathcal{F}, \mathbb{P})^*$ and not necessarily in $L^1(\Omega, \mathcal{F}, \mathbb{P})$; in other words, we cannot be sure that π^* is induced by a probability measure Q , as it may happen that $\pi^* \in L^\infty(\Omega, \mathcal{F}, \mathbb{P})^*$ also has a singular part.

Another drawback, which already appears in the case of finite-dimensional Ω (in which case π^* certainly is induced by some Q with $\frac{dQ}{d\mathbb{P}} = g \in L^1(\Omega, \mathcal{F}, \mathbb{P})$) is the following: we cannot be sure that the function g is strictly positive $\mathbb{P}$ -a.s. or, in other words, that Q is equivalent to $\mathbb{P}$.

After this early work by Ross, a major advance in the theory was achieved between 1979 and 1981 by three seminal papers [14, 15, 24] by Harrison, Kreps, and Pliska. In particular, [14] is a landmark in the field. It uses a similar setting as [29], namely, an ordered topological vector space (X, τ) and a linear functional $\pi : M \rightarrow \mathbb{R}$, where M is a linear subspace of X . Again the question is whether there exists an extension of π to a linear, continuous, strictly positive $\pi^* : X \rightarrow \mathbb{R}$. This question is related in [14] to the issue of whether (M, π) is viable as a model of economic equilibrium. Under proper assumptions on the convexity and continuity of the preferences of agents, this is shown to be equivalent to the extension discussed above.

The paper [14] also analyzes the case when Ω is finite. Of course, only processes $S = (S_t)_{t=0}^T$ indexed by finite, discrete time $\{0, 1, \dots, T\}$ make sense in this case. For this easier setting, the following precise theorem was stated and proved in the subsequent paper [15] by Harrison and Pliska:

Theorem 1 ([Th. 2. 7.] [15]): *suppose the stochastic process $S = (S_t)_{t=0}^T$ is based on a finite, filtered, probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t=0}^T, \mathbb{P})$. The market model contains no-arbitrage possibilities if and only if there is an equivalent martingale measure for S .*

The proof again relies on a (finite-dimensional version) of the Hahn–Banach theorem plus an extra argument making sure to find a measure Q , which is equivalent to $\mathbb{P}$. Harrison and Pliska thus have achieved a precise version of the above meta-theorem in terms of equivalent martingale measures, which does not use the word “essentially”. Actually, the theme of the Harrison–Pliska theorem goes back

much further, to the work of Shimony [35] and Kemeny [22] on symbolic logic in the tradition of Carnap, de Finetti, and Ramsey. These authors showed that, in a setting with only finitely many states of the world, a family of possible bets does not allow (by taking linear combinations) for making a riskless profit (i.e., one certainly does not lose but wins with strictly positive probability), if and only if there is a probability measure Q on these finitely many states, which prices the possible bets by taking conditional Q -expectations.

The restriction to finite Ω is very severe in applications: the flavor of the theory, building on Black–Scholes–Merton, is precisely the concept of *continuous time*. Of course, this involves infinite probability spaces $(\Omega, \mathcal{F}, \mathbb{P})$.

Many interesting questions were formulated in the papers [14, 15] hinting on the difficulties to prove a version of the fundamental theorem of asset pricing beyond the setting of finite probability spaces.

A major breakthrough in this direction was achieved by Kreps [24]: as above, let $M \subseteq X$ and a linear functional $\pi : M \rightarrow \mathbb{R}$ be given. The typical choice for X will now be $X = L^p(\Omega, \mathcal{F}, \mathbb{P})$, for $1 \leq p \leq \infty$, equipped with the topology τ of convergence in norm, or, if $X = L^\infty(\Omega, \mathcal{F}, \mathbb{P})$, equipped with the Mackey topology τ induced by $L^1(\Omega, \mathcal{F}, \mathbb{P})$. This setting will make sure that a continuous linear functional on (X, τ) will be induced by a measure Q , which is absolutely continuous with respect to $\mathbb{P}$.

The no-arbitrage assumption means that $M_0 := \{m \in M : \pi(m) = 0\}$ intersects the positive orthant X_+ of X only in $\{0\}$. In order to obtain an extension of π to a continuous, linear functional $\pi^* : X \rightarrow \mathbb{R}$ we have to find an element in $(X, \tau)^*$, which separates the convex set M_0 from the disjoint convex set $X_+ \setminus \{0\}$, that is, the positive orthant of X with 0 deleted.

Easy examples show that, in general, this is not possible. In fact, this is not much of a surprise (if X is infinite-dimensional) as we know that some topological condition is needed for the Hahn–Banach theorem to work.

It is always possible to separate a *closed* convex set from a disjoint *compact* convex set by a continuous linear functional. In fact, one may even get strict separation in this case. It is this version of the Hahn–Banach theorem that Kreps eventually applies.

But how? After all, neither M_0 nor $X_+ \setminus \{0\}$ are closed in (X, τ) , let alone compact.

Here is the ingenious construction of Kreps: define

$$A = \overline{M_0 - X_+} \quad (5)$$

where the bar denotes the closure with respect to the topology τ . We shall require that A still satisfies

$$A \cap X_+ = \{0\} \quad (6)$$

This property is baptized as “*no free lunch*” by Kreps:

Definition 1 [24]: *The financial market defined by (X, τ) , M , and π admits a free lunch if there are nets $(m_\alpha)_{\alpha \in I} \in M_0$ and $(h_\alpha)_{\alpha \in I} \in X_+$ such that*

$$\lim_{\alpha \in I} (m_\alpha - h_\alpha) = x \quad (7)$$

for some $x \in X_+ \setminus \{0\}$.

It is easy to verify that the negation of the above definition is tantamount to the validity of equation (6).

The economic interpretation of the “no free lunch” condition is a sharpening of the “no-arbitrage condition”. If the latter is violated, we can simply find an element $x \in X_+ \setminus \{0\}$, which also lies in M_0 . If the former fails, we cannot quite guarantee this, but we can find $x \in X_+ \setminus \{0\}$, which *can be approximated* in the τ -topology by elements of the form $m_\alpha - h_\alpha$. The passage from m_α to $m_\alpha - h_\alpha$ means that agents are allowed to “throw away money”, that is, to abandon a positive element $h_\alpha \in X_+$. This combination of the “free disposal” assumption with the possibility of passing to limits is crucial in Kreps’ approach (5) as well as in most of the subsequent literature. It was shown in [Ex. 3.3] [32]; ([33]) that the (seemingly ridiculous) “free disposal” assumption cannot be dropped.

Definition (5) is tailor-made for the application of Hahn–Banach. If the no free lunch condition (6) is satisfied, we may, for any $h \in X_+$, separate the τ -closed, convex set A from the one-point set $\{h\}$ by an element $\pi_h \in (X, \tau)^*$. As $0 \in A$, we may assume that $\pi_h|_A \leq 0$ while $\pi_h(h) > 0$. We thus have obtained a nonnegative (as $-X_+ \subseteq A$), continuous linear functional π_h , which is strictly positive on a given $h \in X_+$. Supposing that X_+ is τ -separable (which is the case in the above setting of L^p -spaces if $(\Omega, \mathcal{F}, \mathbb{P})$ is countably generated), fix a dense sequence $(h_n)_{n=1}^\infty$ and find strictly positive scalars $\mu_n > 0$ such that $\pi^* = \sum_{n=1}^\infty \mu_n \pi_{h_n}$ converges to a

probability measure in $(X, \tau)^* = L^q(\Omega, \mathcal{F}, \mathbb{P})$, where $\frac{1}{p} + \frac{1}{q} = 1$. This yields the desired extension π^* of π which is *strictly positive* on $X_+ \setminus \{0\}$.

We still have to specify the choice of (M_0, π) . The most basic choice is to take for given $S = (S_t)_{0 \leq t \leq T}$ the space generated by the “simple integrands” (3) as proposed in [14]. We thus may deduce from Kreps’ arguments in [24] the following version of the fundamental theorem of asset pricing.

Theorem 2 *Let $(\Omega, \mathcal{F}, \mathbb{P})$ be countably generated and $X = L^p(\Omega, \mathcal{F}, \mathbb{P})$ endowed with the norm topology τ , if $1 \leq p < \infty$, or the Mackey topology induced by $L^1(\Omega, \mathcal{F}, \mathbb{P})$, if $p = \infty$.*

Let $S = (S_t)_{0 \leq t \leq T}$ be a stochastic process taking values in X . Define $M_0 \subseteq X$ to consist of the simple stochastic integrals $\sum_{i=1}^n H_i(S_{t_i} - S_{t_{i-1}})$ as in equation (3).

Then the “no free lunch” condition (5) is satisfied if and only if there is a probability measure Q with $\frac{dQ}{d\mathbb{P}} \in L^q(\Omega, \mathcal{F}, \mathbb{P})$, where $\frac{1}{p} + \frac{1}{q} = 1$, such that $(S_t)_{0 \leq t \leq T}$ is a Q -martingale.

This remarkable theorem of Kreps sets new standards. For the first time, we have a mathematically precise statement of our meta-theorem applying to a general class of models *in continuous time*. There are still some limitations, however.

When applying the theorem to the case $1 \leq p < \infty$, we find the requirement $\frac{dQ}{d\mathbb{P}} \in L^q(\Omega, \mathcal{F}, \mathbb{P})$ for some $q > 1$, which is not very pleasant. After all, we want to know what exactly corresponds (in terms of some no-arbitrage condition) to the existence of an equivalent martingale measure Q . The q -moment condition is unnatural in most applications. In particular, it is not invariant under equivalent changes of measures as is done often in the applications.

The most interesting case of the above theorem is $p = \infty$. However, in this case, the requirement $S_t \in X = L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ is unduly strong for most applications. In addition, for $p = \infty$, we run into the subtleties of the Mackey topology τ (or the weak-star topology, which does not make much of a difference) on $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$. We shall discuss this issue below.

The “heroic period” of the development of the fundamental theorem of asset pricing marked by Ross [29], Harrison–Kreps [14], Harrison–Pliska [15], and Kreps [24], put the issue on safe mathematical grounds and brought some spectacular results. However, it still left many questions open; quite a number

of them were explicitly stated as open problems in these papers.

Subsequently a rather extensive literature developed, answering these problems and opening new perspectives. We cannot give a full account on all of this literature and refer, for example, to the monograph [11] for more extensive information. We can give an outline.

As regards the situation for $1 \leq p \leq \infty$ in Kreps’ theorem, this issue was further developed by Duffie and Huang [12] and, in particular, by Stricker [36]. This author related the no free lunch condition of Kreps to a theorem by Yan [37] obtained in the context of the Bichteler–Dellacherie theorem on the characterization of semimartingales. Using Yan’s theorem, Stricker gave a different proof of Kreps’ theorem, which does not need the assumption that $(\Omega, \mathcal{F}, \mathbb{P})$ is countably generated.

A beautiful extension of the Harrison–Pliska theorem was obtained in 1990 by Dalang, Morton, and Willinger [5]. They showed that, for an $\mathbb{R}^d$ -valued process $(S_t)_{t=0}^T$ in finite discrete time, the no-arbitrage condition is indeed equivalent to the existence of an equivalent martingale measure. The proof is surprisingly tricky, at least for the case $d \geq 2$. It is based on the measurable selection theorem (the suggestion to use this theorem is acknowledged to Delbaen). Different proofs of the Dalang–Morton–Willinger theorem have been given in [17, 20, 21, 26, 31].

An important question left unanswered by Kreps was whether one can, in general, replace the use of nets $(m_\alpha - h_\alpha)_{\alpha \in I}$, indexed by α ranging in a general ordered set I , simply by sequences $(m_n - h_n)_{n=1}^\infty$. In the context of continuous processes, $S = (S_t)_{0 \leq t \leq T}$, a positive answer was given by Delbaen in [6], if one is willing to make the harmless modification to replace the deterministic times $0 = t_0 \leq t_1 \leq \dots \leq t_n = T$ in equation (3) by *stopping times* $0 = \tau_0 \leq \tau_1 \leq \dots \leq \tau_n = T$. A second case, where the answer to this question is positive, are processes $S = (S_t)_{t=0}^\infty$ in infinite, discrete time as shown in [32].

The Banach–Steinhaus theorem implies that, for a sequence $(m_n - h_n)_{n=1}^\infty$ converging in $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$ with respect to the weak-star (or Mackey) topology, the norms $(\|m_n - h_n\|_\infty)_{n=1}^\infty$ remain bounded (“uniform boundedness principle”). Therefore, it follows that in the above two cases of continuous processes $S = (S_t)_{0 \leq t \leq T}$ or processes $(S_t)_{t=0}^\infty$ in infinite, discrete time, the “no free lunch” condition of Kreps can be equivalently replaced by the “no free lunch

with bounded risk” condition introduced in [32]: in equation (7) above, we additionally impose that $(\|m_\alpha - h_\alpha\|_\infty)_{\alpha \in I}$ remains bounded. In this case, we have that there is a constant $M > 0$ such that $m_\alpha \geq -M$, $\mathbb{P}$ -a.s. for each $\alpha \in I$, which explains the wording “bounded risk”.

However, in the context of general semimartingale models $S = (S_t)_{0 \leq t \leq T}$, a counter-example was given by Delbaen and the author in ([Ex. 7.8] [7]) showing that the “no free lunch with bounded risk” condition does not imply the existence of an equivalent martingale measure. Hence, in a general setting and by only using simple integrals, there is no possibility of getting any more precise information on the free lunch condition than the one provided by Kreps’ theorem.

At this stage it became clear that, in order to obtain sharper results, one has to go beyond the framework of simple integrals (3) and rather use general stochastic integrals (1). After all, the simple integrals are only a technical gimmick, analogous to step functions in measure theory. In virtually all the applications, for example, the replication strategy of an option in the Black–Scholes model, one uses general integrals of the form (1).

General integrands pose a number of questions to be settled. First of all, the integral (1) has to be mathematically well defined. The theory of stochastic calculus starting with K. Itô, and developed in particular by the Strasbourg school of probability around Meyer, provides very precise information on this issue: there is a good integration theory for a given stochastic process $S = (S_t)_{0 \leq t \leq T}$ if and only if S is a semimartingale (theorem of Bichteler–Dellacherie).

Hence, mathematical arguments lead to the model assumption that S has to be a semimartingale. However, what about an economic justification of this assumption? Fortunately, the economic reasoning hints in the same direction. It was shown by Delbaen and the author that, for a locally bounded stochastic process $S = (S_t)_{0 \leq t \leq T}$, a very weak form of Kreps’ “no free lunch” condition involving simple integrands (3), implies already that S is a semimartingale (see [Theorem 7.2] [7], for a precise statement).

Hence, it is natural to assume that the model $S = (S_t)_{0 \leq t \leq T}$ of stock prices is a semimartingale so that the stochastic integral (3) makes sense mathematically, for all S -integrable, predictable processes $H = (H_t)_{0 \leq t \leq T}$. As pointed out, [14, 15] impose, in addition, an admissibility condition to rule out doubling strategies and similar schemes.

Definition 2 ([Def. 2.7] [7]): An S -integrable predictable process $H = (H_t)_{0 \leq t \leq T}$ is called *admissible* if there is a constant $M > 0$ such that

$$\int_0^t H_u dS_u \geq -M, \quad \text{a.s., for } 0 \leq t \leq T \quad (8)$$

The economic interpretation is that the economic agent, trading according to the strategy, has to respect a finite credit line M .

Let us now sketch the approach of [7]. Define

$$K = \left\{ \int_0^T H_t dS_t : H \text{ admissible} \right\} \quad (9)$$

which is a set of (equivalence classes of) random variables. Note that by equation (6) the elements $f \in K$ are uniformly bounded from below, that is, $f \geq -M$ for some $M \geq 0$. On the other hand, there is no reason why the positive part f_+ should obey any boundedness or integrability assumption.

As a next step, we “allow agents to throw away money” similarly as in Kreps’ work [24]. Define

$$\begin{aligned} C &= \{g \in L^\infty(\Omega, \mathcal{F}, \mathbb{P}) : g \leq f \text{ for some } f \in K\} \\ &= [K - L_+^0(\Omega, \mathcal{F}, \mathbb{P})] \cap L^\infty(\Omega, \mathcal{F}, \mathbb{P}) \end{aligned} \quad (10)$$

where $L_+^0(\Omega, \mathcal{F}, \mathbb{P})$ denotes the set of nonnegative measurable functions.

By construction, C consists of bounded random variables, so that we can use the functional analytic duality theory between L^∞ and L^1 . The difference of the subsequent definition to Kreps’ approach is that it pertains to the norm topology $\|\cdot\|_\infty$ rather than to the Mackey topology on $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$.

Definition 3 ([2.8] [11]): A locally bounded semimartingale $S = (S_t)_{0 \leq t \leq T}$ satisfies the *no free lunch with vanishing risk condition* if

$$\bar{C} \cap L_+^\infty(\Omega, \mathcal{F}, \mathbb{P}) = \{0\} \quad (11)$$

where $\bar{C}$ denotes the $\|\cdot\|_\infty$ -closure of C .

Here is the translation of equation (11) into prose: the process S fails the above condition if there is a function $g \in L_+^\infty(\Omega, \mathcal{F}, \mathbb{P})$ with $\mathbb{P}[g > 0] > 0$ and a sequence $(f^n)_{n=1}^\infty$ of the form

$$f^n = \int_0^T H_t^n dS_t \quad (12)$$

where H^n are admissible integrands, such that

$$f_n \geq g - \frac{1}{n} \quad a.s. \quad (13)$$

Hence the condition of no free lunch with vanishing risk is intermediate between the (stronger) no free lunch condition of Kreps and the (weaker) no-arbitrage condition. The latter would require that there is a nonnegative function g with $\mathbb{P}[g > 0] > 0$, which is of the form

$$g = \int_0^T H_t dS_t \quad (14)$$

for an admissible integrand H . Condition (13) does not quite guarantee this, but something — at least from an economic point of view — very close: we can *uniformly* approximate from below such a g by the outcomes f_n of admissible trading strategies.

The main result of Delbaen and the author [7] reads as follows.

Theorem 3 ([Corr. 1.2] [7]): *Let $S = (S_t)_{0 \leq t \leq T}$ be a locally bounded real-valued semimartingale.*

There is a probability measure Q on $(\Omega, \mathcal{F})$, which is equivalent to $\mathbb{P}$ and under which S is a local martingale if and only if S satisfies the condition of no free lunch with vanishing risk.

This is a mathematically precise theorem, which, in my opinion, is quite close to the vague “meta-theorem” at the beginning of this article. The difference to the intuitive “no arbitrage” idea is that the agent has to be willing to sacrifice (at most) the quantity $\frac{1}{n}$ in equation (13), where we may interpret $\frac{1}{n}$ as, say, 1 cent.

The proof of the above theorem is rather long and technical and a more detailed discussion goes beyond the scope of this article. To the best of the author’s knowledge, no essential simplification of this proof has been achieved so far ([19]).

Mathematically speaking, the statement of the theorem looks very suspicious at first glance: after all, the *no free lunch with vanishing risk* condition pertains to the *norm topology* of $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$. Hence it seems that, when applying the Hahn–Banach theorem, one can only obtain a linear functional in $L^\infty(\Omega, \mathcal{F}, \mathbb{P})^*$, which is not necessarily of the form $\frac{dQ}{d\mathbb{P}} \in L^1(\Omega, \mathcal{F}, \mathbb{P})$, as we have seen in Ross’ work [29].

The reason why the above theorem, nevertheless, is true is a little miracle: it turns out ([Th. 4.2] [7])

that, under the assumption of no free lunch with vanishing risk, the set C defined in equation (10) is *automatically* weak-star closed in $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$. This pleasant fact is not only a crucial step in the proof of the above theorem; maybe even more importantly, it also found other applications. For example, to find general existence results in the theory of utility optimization (see **Expected Utility Maximization: Duality Methods**) it is of crucial importance to have a closedness property of the set over which one optimizes: for these applications, the above result is very useful [23].

Without going into the details of the proof, the importance of certain elements in the set K is pointed out. The admissibility rules out the use of doubling strategies. The opposite of such a strategy can be called a *suicide strategy*. It is the mathematical equivalent of making a bet at the roulette, leaving it as well as all gains on the table as long as one keeps winning, and wait until one loses for the first time. Such strategies, although admissible, do not reflect economic efficiency. More precisely, we define the following.

Definition 4 *An admissible outcome $\int_0^T H_t dS_t$ is called maximal if there is no other admissible strategy H' such that $\int_0^T H'_t dS_t \geq \int_0^T H_t dS_t$ with $\mathbb{P}[\int_0^T H'_t dS_t > \int_0^T H_t dS_t] > 0$*

In the proof of Theorem 6, these elements play a crucial role and the heart of the proof consists in showing that every element in K is dominated by a maximal element. However, besides their mathematical relevance, they also have a clear economic interpretation. There is no use in implementing a strategy that is not maximal as one can do better. Nonmaximal elements can also be seen as bubbles [18].

In Theorem 6, we only assert that S is a *local* martingale under Q . In fact, this technical concept cannot be avoided in this setting. Indeed, fix an S -integrable, predictable, admissible process $H = (H_t)_{0 \leq t \leq T}$ as well as a bounded, predictable, strictly positive process $(k_t)_{0 \leq t \leq T}$. The subsequent identity holds true trivially.

$$\int_0^t H_u dS_u = \int_0^t \frac{H_u}{k_u} d\tilde{S}_u, \quad 0 \leq t \leq T \quad (15)$$

where

$$\tilde{S}_u = \int_0^u k_v dS_v, \quad 0 \leq u \leq T \quad (16)$$

The message of equations (15) and (16) is that the class of processes obtained by taking admissible stochastic integrals on S or $\tilde{S}$ simply coincide. An easy interpretation of this rather trivial fact is that the possible investment opportunities do not depend on whether stock prices are denoted in euros or in cents (this corresponds to taking $k_t \equiv 100$ above).

However, it may very well happen that $\tilde{S}$ is a martingale while S only is a local martingale. In fact, the concept of local martingales may even be *characterized* in these terms ([Proposition 2.5] [10]): a semimartingale S is a local martingale if and only if there is a strictly positive, decreasing, predictable process k such that $\tilde{S}$ defined in equation (16) is a martingale.

Again we want to emphasize the role of the maximal elements. It turns out ([8, 11]) that if $\int_0^T H_t dS_t$ is maximal, *if and only if* there is an equivalent local martingale measure Q such that the process $\int_0^t H_u dS_u$ is a martingale and not just a local martingale under Q . One can show ([9, 11]) that for a given sequence of maximal elements $\int_0^T H_t^n dS_t$, one can find one and the same equivalent local martingale measure Q such that *all* the processes $\int_0^t H_u^n dS_u$ are Q -martingales. Another useful and related characterization ([8, 11]) is that if a process $V_t = x + \int_0^t H_u dS_u$ defines a maximal element $\int_0^T H_u dS_u$ and remains strictly positive, the whole financial market can be rewritten in terms of V as a new numéraire without losing the no-arbitrage properties. The change of numéraire and the use of the maximal elements allows to introduce a numéraire invariant concept of admissibility, see [9] for details. An important result in this article is that the sum of maximal elements is again a maximal element.

Theorem 6 above still contains one severe limitation of generality, namely, the local boundedness assumption on S . As long as we only deal with continuous processes S , this requirement is, of course, satisfied. However, if one also considers processes with jumps, in most applications it is natural to drop the local boundedness assumption.

The case of general semimartingales S (without any boundedness assumption) was analyzed in [10]. Things become a little trickier as the concept of local martingales has to be weakened even further: we refer

to **Equivalent Martingale Measures** for a discussion of the concept of sigma-martingales. This concept allows to formulate a result pertaining to a perfectly general setting.

Theorem 4 ([Corr. 1.2][7]): *Let $S = (S_t)_{0 \leq t \leq T}$ be an $\mathbb{R}^d$ -valued semimartingale.*

There is a probability measure Q on $(\Omega, \mathcal{F})$, which is equivalent to $\mathbb{P}$ and under which S is a sigma-martingale if and only if S satisfies the condition of no free lunch with vanishing risk with respect to admissible strategies.

One may still ask whether it is possible to formulate a version of the fundamental theorem, which does not rely on the concepts of local or sigma-, but rather on “true” martingales.

This was achieved by Yan [38] by applying a clever change of numéraire technique, (see **Change of Numéraire** also [Section 5] [13]): let us suppose that $(S_t)_{0 \leq t \leq T}$ is a *positive* semimartingale, which is natural if we model, for example, prices of shares (while the previous setting of not necessarily positive price processes also allows for the modeling of forwards, futures etc.).

Let us weaken the admissibility condition (8) above, by calling a predictable, S -integrable process *allowable* if

$$\int_0^t H_u dS_u \geq -M(1 + S_t) \quad a.s., \text{ for } 0 \leq t \leq T \quad (17)$$

The economic idea underlying this notion is well known and allows for the following interpretation: an agent holding M units of stock and bond may, in addition, trade in S according to the trading strategy H satisfying equation (17); the agent will then remain liquid during $[0, T]$.

By taking $S + 1$ as new numéraire and replacing admissible by allowable trading strategies, Yan obtains the following theorem.

Theorem 5 ([Theorem 3.2] [38]) *Suppose that S is a positive semimartingale.*

There is a probability measure Q on $(\Omega, \mathcal{F})$, which is equivalent to $\mathbb{P}$ and under which S is a martingale if and only if S satisfies the condition of no free lunch with vanishing risk with respect to allowable trading strategies.

WALTER SCHACHERMAYER

Risk-neutral Pricing

A classical problem arising frequently in business is the valuation of future cash flows that are risky. By the term *risky* we mean that the payment is not of a deterministic nature; rather there is some uncertainty in the amount of the future cash flows. Of course, in real life, virtually everything happening in the future contains some element of uncertainty.

As an example, let us think of an investment project, say, a company plans to build a new factory. A classical way to proceed is to calculate a *net asset value*. One tries to estimate the future cash flows generated by the project in the subsequent periods. In the present example, they will initially be negative; this initial investment should be compensated by the positive cash flows in the later periods. Having fixed these estimates of the future cash flows for all periods, one calculates a *net asset value* by discounting these cash flows to the present date. But, of course, there is uncertainty involved in the estimation of the future cash flows and people doing these calculations are, of course, aware of that. The usual way to compensate for this uncertainty is to apply an interest rate that is higher than the *riskless^a rate of return* corresponding to the rate of return of government bonds.

The spread between the riskless rate of return and the interest rate used for discounting the future cash flows in the calculation of the net asset value can be quite substantial in order to compensate for the riskiness. Only if the net asset value, obtained by discounting with a rather high rate of return, remains positive, the management of the company will engage in the investment project.

Mathematically speaking, the above procedure may be described as follows: first, one determines the *expected values* of the future cash flows and, subsequently, one discounts by using an elevated discount factor. However, there is no systematic way of mathematically approaching the question of how the degree of uncertainty in the determination of the expected values can be quantified, and in which way this should be taken into account to determine the spread between the interest rates.

We now turn to a different approach, which interchanges the roles of taking expectations and discounting in taking the riskness of the cash flows into

account. This approach is used in modern mathematical finance, in particular, in the Black–Scholes formula. However, the idea goes back much further and the method was used by actuaries for centuries.

Think of a life insurance contract. To focus on the essential point, we consider the simplest case: a one-year death insurance. If the insured person dies within the subsequent year, the insured sum S , say $S = €1$, is paid out at the end of this year; if the insured person survives the year, nothing is paid, and the contract ends at the end of the year.

To calculate the premium^b for this contract, actuaries look up in their mortality tables^c the probability that the insured person dies within one year. The traditional notation for this probability is q_x , where x denotes the age of the insured person.

To calculate the premium for such a one-year death insurance contract, with S normalized to $S = 1$, actuaries apply the formula

$$P = \frac{1}{1+i} q_x \quad (1)$$

The term q_x is just the expected value of the future cash flow and i denotes “the” interest rate: hence the premium P is the *discounted expected value* of the cash flow at the end of the year.

It is important to note that actuaries use a “conservative” value for the interest rate, for example, $i = 3\%$. In practical terms, this corresponds quite well to the “riskless rate of return”. In any case, it is quite different, in practical as well as in theoretical terms, from the discount factors used to calculate the net asset value of a risky future cash flow according to the method stated above.

But, after all, the premium of our death insurance contract also corresponds to the present value of an uncertain future cash flow! How do actuaries account for the risk involved in this cash flow, if not *via* an appropriate choice of the interest rate?

The answer is simple when looking at equation (1): apart from the interest rate i the probability q_x of dying within the next year also enters the calculation of P . The art of the actuarial profession is to choose the “good” value for q_x . Typically, actuaries very well know the actual mortality probabilities in their portfolio of contracts, which often consists of several hundred thousand contracts; in other words, they have a very good understanding of what the “true value” of q_x is. However, they do not apply this “true value” in their premium calculations: in equation (1) they

would apply a value for q_x which is substantially higher than the “true” value of q_x . Actuaries speak about mortality tables of the first kind and the second kind.

Mortality tables of the second kind reflect the “true probabilities”. They are only used for the internal analysis of the profitability of the insurance company. On the other hand, in the daily life of actuaries only the mortality tables of the first kind, which properly display the “modified” probabilities q_x , are used. They are not only used for the calculation of premia but also for all quantities of relevance involved in an insurance policy, such as surrender values, reserves, and so on. This constitutes a big strength of the actuarial technique: actuaries are always armed with perfectly coherent logic when doing all these calculations. This logic is that of a fair game or, mathematically speaking, of a martingale. Indeed, *if the q_x would correctly model the mortality of the insured person and if i were the interest rate that the insurance company could precisely achieve when investing the premia, then the premium calculation (1) would make the insurance contract a fair game.*

It is important to note that this argument pertains only to a kind of virtual world, as it is precisely the task of actuaries to choose the mortalities q_x in a prudent way such that they do *not* coincide with the “true” probabilities. In the case of insurance contracts where the insurance company has to pay in the case of death, actuaries choose the probabilities q_x higher than the “true ones”. This happens in the simple example considered above. On the other hand, if the insurance company has to pay when the insured person is still alive, for example, in the case of a pension, actuaries use probabilities q_x which are lower than the “true ones”, in order to be on the safe side.

These actuarial techniques have been elaborated on as this will be helpful to more clearly understand the essence of the option pricing approach of Black, Scholes, and Merton. Their well-known model for the risky stock S and the risk-free bond are

$$\begin{aligned} dS_t &= S_t \mu dt + S_t \sigma dW_t \\ dB_t &= B_t r dt \end{aligned} \quad (2)$$

The task is to value a (European) derivative on the stock S at expiration time T , for example, $C_T = (S_T - K)_+$. As explained earlier (see **Complete**

Markets), the solution proposed by Black, Scholes, and Merton is

$$C_0 = e^{-rT} \mathbb{E}_Q[C_T] \quad (3)$$

The above equation is a perfect analog to the premium of a death insurance contract (1). The first term, taking care of the discounting, uses the “conservative” choice of a riskless interest rate r . The second term gives the expected value of the future cash flow, taken under the *risk-neutral* probability measure Q . This probability measure Q is chosen in such a way that the dynamics (2) of the stock under Q become

$$dS_t = S_t r dt + S_t \sigma dW_t \quad (4)$$

The point is that the drift term $S_t r dt$ of S under Q is in line with the growth rate of the risk-free bond

$$dB_t = B_t r dt \quad (5)$$

The interpretation of (4) is that *if the market were correctly modeled by the probability Q* , then the market was *risk neutral*. The mathematical formulation, $(e^{-rt} S_t)_{0 \leq t \leq T}$, that is, the stock price process discounted by the risk-free interest rate r , is a martingale under Q .

Similarly as in the actuarial context above, the mathematical model of a financial market under the risk-neutral measure Q pertains to a virtual world, and not to the real world. In reality, that is, under $\mathbb{P}$, we would typically have $\mu > r$. Fixing this case, Girsanov’s formula (see **Equivalence of Probability Measures; Stochastic Exponential**) tells us precisely that the probability measure Q represents a “prudent choice of probability”. It gives less weight than the original measure $\mathbb{P}$ to the events which are favorable for the buyer of a stock, that is, when S_T is large. On the other hand, Q gives more weight than $\mathbb{P}$ to unfavorable events, that is, when S_T is small. This can be seen from Girsanov’s formula

$$\frac{dQ}{d\mathbb{P}} = \exp \left[-\frac{\mu - r}{\sigma} W_T - \frac{(\mu - r)^2}{2\sigma^2} T \right] \quad (6)$$

and the dynamics of the stock price process S under $\mathbb{P}$ resulting from (2)

$$S_T = S_0 \exp \left[\sigma W_T + \left(\mu - \frac{\sigma^2}{2} \right) T \right] \quad (7)$$

Fixing a random element $\omega \in \Omega$, the Radon–Nikodym derivative $\frac{dQ}{dP}(\omega)$ is small iff $W_T(\omega)$ is large, and the latter is large iff $S_T(\omega)$ is large.

In many applications, it is not even necessary to consider the original “true” probability measure $\mathbb{P}$. There are hundreds of papers containing the sentence: “we work under the risk-neutral measure Q ”. This is parallel to the situation of an actuary in his/her daily work: He/she does not bother about the “true” mortality probabilities, but only about the probabilities listed in the mortality table of the first kind.

The history of the valuation formula (3), in fact, goes back much further than Black, Scholes, and Merton. Already in 1900, L. Bachelier applied this formula in his thesis [1] in order to price options. It seems worthwhile to have a closer look. Bachelier did not use a discount factor, such as e^{-rT} , in equation (3). The reason is that in 1900 prices underlying the option were denoted in forward prices at the Paris stock exchange (called “true prices” by Bachelier who also carefully adjusted for coupon payments; see [6] for details). As it is well known, when considering forward prices the discount factor disappears. In modern terminology, this fact boils down to “Black’s formula”.

As regards the second term in equation (3), Bachelier started from the very beginning with a martingale model, namely, (scaled) Brownian motion [6]

$$S_t = S_0 + \sigma W_t, \quad 0 \leq t \leq T \quad (8)$$

In other words, he also “worked assuming the risk-neutral probability”.

In fact, in the first pages of his thesis Bachelier does speak about *two kinds of probabilities*. The following is a quote from [1]:

- (i) The probability which might be called “mathematical”, which can be determined a priori and which is studied in games of chance.
 - (ii) The probability dependent on future events and, consequently impossible to predict in a mathematical manner.
- This latter is the probability that the speculator tries to predict.

Admitting a large portion of goodwill and hindsight knowledge one might interpret (i) something like the risk-neutral probability Q , while (ii) describes something like the historical measure $\mathbb{P}$.

Risk-neutral Pricing for General Models

In the Black–Scholes model (2) there is only one *risk-neutral* measure Q under which the discounted stock price process becomes a martingale.^d

This feature characterizes *complete financial markets* (see **Complete Markets**). In this case, we not only obtain from equation (3) a price C_0 for the derivative security C_T , but we get much more: the derivative can be perfectly replicated by starting at time $t = 0$ with the initial investment given by equation (3) and subsequent dynamical trading in the underlying stock S . This is the essence of the approach of Black, Scholes, and Merton; it has no parallel in the classical actuarial approach or in the work of L. Bachelier.

What happens in incomplete financial markets, that is, when there is more than one risk-neutral measure Q ? It has been shown by Harrison and Pliska [4] that equation (3) yields *precisely* all the *consistent pricing rules* for derivatives on S , when Q runs through the set of risk-neutral measures equivalent to $\mathbb{P}$. We denote the latter set by $\mathcal{M}^e(S)$. The term *consistent* means that there should be no-arbitrage possibilities when all possible derivatives on S are traded at the price given by equation (3).

But, what is the good choice of $Q \in \mathcal{M}^e(S)$? In general, this question is as meaningless as the question: what is the good choice of an element in some convex subset of a vector space? In order to allow for a more intelligent version of this question, one needs additional information. It is here that the original probability measure $\mathbb{P}$ comes into play again: a popular approach is to choose the element $Q \in \mathcal{M}^e(S)$ which is “closest” to $\mathbb{P}$.

In order to make this idea precise, fix a strictly convex function $V(y)$, for example,

$$V(y) = y(\ln(y) - 1), \quad y > 0 \quad (9)$$

$$\text{or} \quad V(y) = \frac{y^2}{2}, \quad y \in \mathbb{R} \quad (10)$$

Determine $\hat{Q} \in \mathcal{M}^e(S)$ as the optimizer of the optimization problem

$$\mathbb{E} \left[V \left(\frac{dQ}{dP} \right) \right] \rightarrow \min! \quad Q \in \mathcal{M}^e(S) \quad (11)$$

To illustrate things at the hand of the above examples: For $V(y) = y(\ln(y) - 1)$, this corresponds to

choosing the element $\hat{Q} \in \mathcal{M}^e(S)$ minimizing the relative entropy $H(Q|\mathbb{P}) = \mathbb{E}_Q\left[\ln\left(\frac{dQ}{d\mathbb{P}}\right)\right]$; for $V(y) = \frac{y^2}{2}$, this corresponds to choosing $Q \in \mathcal{M}^e(S)$ minimizing the L^2 -norm $\|\frac{dQ}{d\mathbb{P}}\|_{L^2(\mathbb{P})} = \mathbb{E}_{\mathbb{P}}\left[\left(\frac{dQ}{d\mathbb{P}}\right)^2\right]^{\frac{1}{2}}$.

Under appropriate conditions, the minimization problem (11) has a solution, which then is unique by the strict convexity assumption.

There is an interesting connection to the issue of **Utility Indifference Valuation**. Let $U(x)$ be the (negative) Legendre–Fenchel transform of V , that is,

$$U(x) = \inf_y \{-xy + V(y)\} \quad (12)$$

For the two examples above, we obtain

$$U(x) = -e^{-x} \quad (13)$$

$$\text{or } U(x) = -\frac{x^2}{2} \quad (14)$$

which may be interpreted as utility functions. It turns out that—under appropriate assumptions—the optimizer $\hat{Q}$ in equation (11) yields precisely the marginal utility indifference pricing rule when plugged into equation (3) (see **Utility Indifference Valuation**).

In particular, we may conclude that pricing by marginal utility [2, 3, 5] is a consistent pricing rule in the sense of Harrison and Kreps.

End Notes

^aIn real life nothing is actually *riskless*: in practice, the *riskless rate of return* corresponds to government bonds (provided that the government is reliable).

^bWe do not consider costs, taxes, and so on, which are eventually added to this premium; we only consider the “net premium”.

^cA mortality table (horrible word!) is nothing but a list of probabilities q_x , where x runs through the relevant ages, say $x = 18, \dots, 110$. The first mortality table was constructed by Edmond Halley in 1693.

^dTo be precise: this result only holds true if for the underlying filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$ we have $\mathcal{F} = \mathcal{F}_T$ and the filtration $(\mathcal{F}_t)_{0 \leq t \leq T}$ is generated by $(S_t)_{0 \leq t \leq T}$.

Hedging

In a complete market (*see Complete Markets*) derivative securities are redundant in the sense that they can be replicated by the gains from trading *via* a self-financing admissible strategy in the underlying asset. This replicating strategy is then called the *hedging strategy* for the claim.

More formally, we fix some filtered probability space $(\Omega, \mathcal{A}, (\mathcal{F}_t), P)$. The (discounted) price process of a risky asset is modeled by an $(\mathcal{F}_t)$ -adapted semimartingale S . A *claim* B is an $\mathcal{F}_T$ -measurable random variable, where T is the maturity of the claim. B is *attainable* if there exists a constant c and an admissible strategy ϑ such that

$$B = c + \int_0^T \vartheta_t dS_t \quad (1)$$

The quintuple $(\Omega, \mathcal{A}, (\mathcal{F}_t), P, S)$ models a financial market. A market is *complete* if all bounded claims are attainable. Finally, a market that is not complete is called *incomplete*.

In case there exists an equivalent martingale measure (*see Equivalent Martingale Measures*) Q for S in a complete market, it must be unique according to some version of the second fundamental theorem of asset pricing (*see Second Fundamental Theorem of Asset Pricing*). Moreover, S has the predictable representation property (PRP) (*see Martingale Representation Theorem*) with respect to (w.r.t.) $(Q, (\mathcal{F}_t))$, meaning that every $(Q, (\mathcal{F}_t))$ -martingale can be written as a sum of its initial value and a stochastic integral w.r.t. S . These facts can be used to show existence of an optimal hedging strategy as follows: we consider for each bounded claim B the associated Q -martingale V given by

$$V_t = E_Q[B | \mathcal{F}_t], \quad t \leq T \quad (2)$$

By the PRP, there exists an admissible strategy ϑ such that

$$V_t = V_0 + \int_0^t \vartheta_u dS_u, \quad t \leq T \quad (3)$$

In particular, for $t = T$, we get

$$B = E_Q[B] + \int_0^T \vartheta_t dS_t \quad (4)$$

To calculate ϑ , note that we can express ϑ as the (symbolic) differential of angle bracket processes (w.r.t. Q),

$$\vartheta_t = \frac{d \langle V, S \rangle_t}{d \langle S \rangle_t} \quad (5)$$

which then in turn can often be evaluated by assuming more specific structures for the price process S and the claim B .

Quadratic Risk Minimization

In incomplete markets, one can in general not hedge a claim perfectly, and hence, there will always be some remaining risk which can be minimized according to various criteria. The Föllmer–Sondermann (FS) [5] approach consists in an orthogonal projection in $L^2(Q)$ of a square-integrable claim B onto the subspace spanned by the constants and stochastic integrals w.r.t. the price process S (which we assume to be locally square-integrable). Here, Q is some martingale measure for S that has been obtained either *via* calibration or according to some optimality criterion.

More precisely, given a claim $B \in L^2(Q, \mathcal{F}_T)$, we want to minimize

$$E_Q \left[\left(B - c - \int_0^T \vartheta_t dS_t \right)^2 \right] \quad (6)$$

over all constants c and all $\vartheta \in L^2(S)$, that is, predictable processes ϑ , such that $E_Q \left[\int_0^T \vartheta_t^2 d[S]_t \right] < \infty$. Hence, the goal is to project B onto the linear space

$$K = \left\{ c + \int_0^T \vartheta_t dS_t : c \in \mathbb{R}, \vartheta \in L^2(S) \right\} \subset L^2(Q) \quad (7)$$

For ϑ as above we also denote

$$K_0 = \left\{ \int_0^T \vartheta_t dS_t : \vartheta \in L^2(S) \right\} \subset L^2(Q) \quad (8)$$

By its very construction, the stochastic integral yields an isometry (here, we understand $[S]$ as the measure on $[0, T]$ which is associated with the increasing process $[S]$)

$$K_0 \cong L^2(\Omega \times [0, T], Q \otimes [S]) \quad (9)$$

$$\int_0^T \vartheta_t dS_t \longleftrightarrow \vartheta \quad (10)$$

since we have

$$E_Q \left[\left(\int_0^T \vartheta_t dS_t \right)^2 \right] = E_Q \left[\int_0^T \vartheta_t^2 d[S]_T \right] \quad (11)$$

Hence, K_0 is isometrically isomorphic to an L^2 -space and therefore closed. Therefore, we can apply the theorem about the orthogonal projection in the Hilbert spaces to get a decomposition

$$B = c^B + \int_0^T \vartheta_t^B dS_t + L_T \quad (12)$$

where L_T is orthogonal to each element of K ; in particular, $E_Q[L_T] = 0$ since $1 \in K$. It follows that we have $c^B = E_Q[B]$, and ϑ^B is called the *FS optimal hedging strategy*. As processes, $L_t := E[L_T | \mathcal{F}_t]$ and S are strongly orthogonal in the sense that LS is a Q -martingale or equivalently, $\langle L, S \rangle = 0$, where the predictable covariation $\langle \cdot, \cdot \rangle$ here, refers to the measure Q . This implies

$$\int \vartheta^B d\langle V, S \rangle = \langle S, S \rangle \quad (13)$$

where $V_t := E_Q[B | \mathcal{F}_t]$ denotes the martingale generated by B . Moreover, a simple calculation yields

$$E_Q[L_T^2] = E_Q \left[\langle V, V \rangle_T - \int_0^T (\vartheta_t^B)^2 \langle S, S \rangle_t \right] \quad (14)$$

Equation (13) is sometimes written as

$$\vartheta^B = \frac{d\langle V, S \rangle}{d\langle S, S \rangle} \quad (15)$$

We call

$$V = c^B + \int \vartheta^B dS + L \quad (16)$$

the *Galtchouk–Kunita–Watanabe* (GKW) decomposition of B or rather V relative to S .

In some models, one can compute the optimal (risk-minimizing) hedging strategy by solving a partial integro-differential equation [1] or by a generalized Clark–Ocone formula from Malliavin calculus [2].

Utility-indifference Hedging

Let u be some utility function defined on the whole real line. If there exists a number π satisfying

$$\begin{aligned} & \sup_{\vartheta} E \left[u \left(x + \int_0^T \vartheta_t dS_t \right) \right] \\ &= \sup_{\vartheta} E \left[u \left(x + \int_0^T \vartheta_t dS_t + \pi - B \right) \right] \end{aligned} \quad (17)$$

then it is called *utility-indifference price* of the claim B . It is the threshold where the investor is indifferent whether just to maximize expected utility from a pure investment into the stock with the price process S or to sell in addition a claim B and collect a premium π for this.

The optimal strategies ϑ on both sides of equation (17) typically differ. The difference

$$\theta := \phi^B - \phi^0 \quad (18)$$

of the optimizers on the right- and the left-hand side respectively can be interpreted as a *utility-based hedging strategy*. It corresponds to the adjustment of the investor's portfolio made in order to account for the option.

Let us consider exponential utility

$$u(x) = 1 - \exp(-\alpha x) \quad (19)$$

where $\alpha > 0$. If θ^α denotes the exponential utility-based hedging strategy corresponding to selling α units of the claim B , then it turns out that under quite general conditions the associated normalized gains $\frac{1}{\alpha} \int_0^T \theta_t^\alpha dS_t$ converge in $L^2(Q^0)$, Q^0 being the minimal entropy martingale measure, to $\int_0^T \vartheta_t^B dS_t$. Here, ϑ^B is the integrand coming from the GKW decomposition (12) w.r.t. Q^0 ; see [6] and the references contained therein.

Further Approaches to Hedging

Ideally, one would like to find a hedging strategy that always allows one to superreplicate the claim B . Finding such a strategy is related to the optional decomposition theorem for supermartingales which are bounded from below. However, it turns out that pursuing such a *superhedging strategy* is too expensive in the sense that the corresponding price

typically equals the highest price consistent with no-arbitrage pricing, that is, it amounts to $\sup_Q E_Q[B]$, where the supremum is taken over all the equivalent martingale measures Q .

Therefore, it has been proposed by Föllmer and Leukert [3] to maximize the probability of a successful hedge given a certain amount of initial capital, a concept that they call *quantile hedging*. However, with this approach there is no protection for the worst case scenarios other than portfolio diversification, and technically, it might be difficult to implement this since it corresponds to hedging a knock-out option. The same authors [4], moreover, considered *efficient hedges* which minimize the expected shortfall weighted by some loss function. In this way, the investor may interpolate between the extremes of no hedge and a superhedge, depending on the accepted level of shortfall risk.

Complete Markets

According to the arbitrage pricing of derivative securities, the arbitrage price of a financial derivative is defined as the wealth of a self-financing trading strategy based on traded primary assets, which replicates the terminal payoff at maturity (or, more generally, all cash flows) from the financial derivative. Hence, an important issue arises whether any financial derivative admits a replicating strategy in a given model; if this property holds, then the market model is said to be *complete*. Completeness of a market model ensures that any derivative security can be priced by arbitrage and hedged by a dynamic trading in primary traded assets. For example, in the framework of the Cox, Ross, and Rubinstein [9] model, not only the call and put options but also any path-independent or path-dependent contingent claim can be replicated by a dynamic trading in stock and bond. Similarly, the classic Black and Scholes [3] model enjoys the property of completeness, although a suitable technical assumption needs to be imposed on the class of considered contingent claims.

Even for an incomplete model, the class of hedgeable derivatives, formally represented by *attainable* contingent claims, can be sufficiently large for practical purposes. Therefore, completeness should not be seen as a necessary requirement, as opposed to the no-arbitrage property, which is an indispensable feature of any financial model used for arbitrage pricing of derivative securities.

Finite Market Models

The issue of completeness of a *finite* market model was analyzed, among others, by Taqqu and Willinger [24]. The finiteness of a market means that the underlying probability space is finite, $\Omega = \{\omega_1, \omega_2, \dots, \omega_d\}$, and trading activities may only occur at the finite set of dates, denoted as $\{0, 1, \dots, T\}$. As a standard example of a finite market model, one may quote, for instance, the Cox, Ingersoll, and Ross [9] binomial tree model (*see Binomial Tree*) or any its multinomial extensions.

Let $S^1, S^2, \dots, S^k$ be the stochastic processes describing the *spot* (or *cash*) prices of some non-dividend paying financial assets. As customary, we postulate that the price process of at least one asset

is given as a strictly positive process, so that it can be selected as a *numéraire asset*. Let us then assume that $S_t^k > 0$ for every $t \leq T$. To emphasize the special role of the process S^k , we will sometimes write B instead of S^k . We assume that all assets are perfectly divisible and the market is frictionless, that is, there are no restrictions on the short-selling of assets, transaction costs, taxes, and so on.

We consider a probability space $(\Omega, \mathcal{F}_T, \mathbb{P})$, which is equipped with a filtration $\mathbb{F} = (\mathcal{F}_t)_{t \leq T}$. A probability measure $\mathbb{P}$, to be interpreted as the real-life probability, is an arbitrary probability measure on $(\Omega, \mathcal{F}_T)$ such that $\mathbb{P}(\omega_i) > 0$ for every $i = 1, 2, \dots, d$. For convenience, we assume throughout that the σ -field $\mathcal{F}_0$ is trivial, that is, $\mathcal{F}_0 = \{\emptyset, \Omega\}$. All processes considered in what follows are assumed to be $\mathbb{F}$ -adapted.

Trading Strategies

The component ϕ_t^i of a trading strategy $\phi = (\phi^1, \phi^2, \dots, \phi^k)$ represents the number of units of the i th security held by an investor at time t . In other words, $\phi_t^i S_t^i$ is the amount of funds invested in the i th security at time t . Hence, the *wealth process* $V(\phi)$ of a trading strategy ϕ is given by the equality, for $t = 0, 1, \dots, T$,

$$V_t(\phi) = \sum_{i=1}^k \phi_t^i S_t^i \quad (1)$$

The initial wealth $V_0(\phi) = \phi_0 S_0$ is also referred to as the *initial cost* of ϕ .

A trading strategy ϕ is said to be *self-financing* whenever it satisfies the following condition, for every $t = 0, 1, \dots, T-1$,

$$\sum_{i=1}^k \phi_t^i S_{t+1}^i = \sum_{i=1}^k \phi_{t+1}^i S_{t+1}^i \quad (2)$$

In the financial interpretation, this condition means that the portfolio ϕ is revised at any date t in such a way that there are no infusions of external funds and no funds are withdrawn from the portfolio. We denote by Φ the vector space of all self-financing trading strategies. The *gains process* $G(\phi)$ of any trading strategy ϕ equals, for $t = 0, 1, \dots, T$,

$$G_t(\phi) = \sum_{u=0}^{t-1} \sum_{i=1}^k \phi_u^i (S_{u+1}^i - S_u^i) \quad (3)$$

with $G_0(\phi) = 0$. It can be checked that a trading strategy ϕ is self-financing if and only if the equality $V_t(\phi) = V_0(\phi) + G_t(\phi)$ holds for every $t = 0, 1, \dots, T$.

Replication and Arbitrage

A European contingent claim X with maturity T is an arbitrary $\mathcal{F}_T$ -measurable random variable. Since the space Ω is assumed to be a finite set with d elements, any claim X has the representation $X = (X(\omega_1), X(\omega_2), \dots, X(\omega_d)) \in \mathbb{R}^d$. Hence, the class $\mathcal{X}$ of all contingent claims that settle at T may be identified with the vector space $\mathbb{R}^d$.

A *replicating strategy* for the contingent claim X , which settles at time T , is a self-financing trading strategy ϕ such that $V_T(\phi) = X$. For any claim X , we denote by Φ_X the class of all replicating strategies for X .

The wealth process $V(\phi)$ of an arbitrary strategy ϕ from Φ_X is called a *replicating process* of X in $\mathcal{M}$. Finally, we say that a claim X is *attainable* in $\mathcal{M}$ if it admits at least one replicating strategy. We denote the class of all attainable claims by $\mathcal{A}$.

Definition 1 A market model $\mathcal{M}$ is said to be complete if every claim $X \in \mathcal{X}$ is attainable in $\mathcal{M}$ or, equivalently, if for every $\mathcal{F}_T$ -measurable random variable X there exists at least one trading strategy $\phi \in \Phi$ such that $V_T(\phi) = X$. In other words, a market model $\mathcal{M}$ is complete whenever $\mathcal{X} = \mathcal{A}$.

Let X be an arbitrary attainable claim that settles at time T . We say that X is *uniquely replicated* in $\mathcal{M}$ if it admits a unique replicating process in $\mathcal{M}$, that is, if the equality $V_t(\phi) = V_t(\psi)$, $t \in [0, T]$, holds for arbitrary trading strategies ϕ, ψ from Φ_X . Then the process $V(\phi)$ is termed the *wealth process* of X in $\mathcal{M}$.

Arbitrage Price

A trading strategy $\phi \in \Phi$ is called an *arbitrage opportunity* if $V_0(\phi) = 0$ and the terminal wealth of ϕ satisfies

$$\mathbb{P}(V_T(\phi) \geq 0) = 1 \quad \text{and} \quad \mathbb{P}(V_T(\phi) > 0) > 0 \quad (4)$$

where $\mathbb{P}$ is the real-world probability measure. We say that a market $\mathcal{M} = (S, \Phi)$ is *arbitrage free* if

there are no-arbitrage opportunities in the class Φ of all self-financing trading strategies.

It can be shown that if the market model $\mathcal{M}$ is arbitrage free, then any attainable contingent claim X is uniquely replicated in $\mathcal{M}$. The converse implication is not true, however, that is, the uniqueness of the wealth process of any attainable contingent claim does not imply the arbitrage-free property of a market, in general. Therefore, the existence and uniqueness of the wealth process associated with any attainable claim is insufficient to justify the term *arbitrage price*. Indeed, it is easy to give an example of a finite market in which all claims can be uniquely replicated, but there exists a strictly positive claim which can be replicated by a self-financing strategy with a negative initial cost.

Definition 2 Let the market model $\mathcal{M}$ be arbitrage free. Then the wealth process of an attainable claim X is called the *arbitrage price* of X in $\mathcal{M}$ and it is denoted by $\pi_t(X)$ for every $t = 0, 1, \dots, T$.

Risk-neutral Valuation Formula

Recall that we write $S^k = B$. Let us denote by S^* the process of *relative prices*, which equals, for every $t = 0, 1, \dots, T$,

$$\begin{aligned} S_t^* &= (S_t^1 B_t^{-1}, S_t^2 B_t^{-1}, \dots, S_t^k B_t^{-1}) \\ &= (S_t^{*1}, S_t^{*2}, \dots, S_t^{*(k-1)}, 1) \end{aligned} \quad (5)$$

where we denote $S^{*i} = S^i B^{-1}$. Recall that the probability measures $\mathbb{P}$ and $\mathbb{Q}$ on $(\Omega, \mathcal{F})$ are said to be *equivalent* if, for any event $A \in \mathcal{F}$, the equality $\mathbb{P}(A) = 0$ holds if and only if $\mathbb{Q}(A) = 0$. Similarly, $\mathbb{Q}$ is said to be *absolutely continuous* with respect to $\mathbb{P}$ if, for any event $A \in \mathcal{F}$, the equality $\mathbb{P}(A) = 0$ implies that $\mathbb{Q}(A) = 0$. Clearly, if the probability measures $\mathbb{P}$ and $\mathbb{Q}$ are equivalent, then they are also equivalent to each other. The following concept is crucial in the so-called risk-neutral valuation approach.

Definition 3 A probability measure $\mathbb{P}^*$ on $(\Omega, \mathcal{F}_T)$ equivalent to $\mathbb{P}$ (absolutely continuous with respect to $\mathbb{P}$, respectively) is called a *equivalent martingale measure* for S^* (a *generalized martingale measure* for S^* , respectively) if the relative price S^* is a $\mathbb{P}^*$ -martingale with respect to the filtration $\mathbb{F}$.

An $\mathbb{F}$ -adapted, k -dimensional process $S^* = (S^{*1}, S^{*2}, \dots, S^{*k})$ is a $\mathbb{P}^*$ -martingale with respect to a filtration $\mathbb{F}$ if the equality

$$\mathbb{E}_{\mathbb{P}^*}(S_{t+1}^{*i} | \mathcal{F}_t) = S_t^{*i} \quad (6)$$

holds for every i and $t = 0, 1, \dots, T-1$.

We denote by $\mathcal{P}(S^*)$ and $\mathcal{Q}(S^*)$ the class of all equivalent martingale measures for S^* and the class of all generalized martingale measures for S^* , respectively, so that the inclusion $\mathcal{P}(S^*) \subseteq \mathcal{Q}(S^*)$ holds. It is not difficult to provide an example in which the class $\mathcal{P}(S^*)$ is empty, whereas the class $\mathcal{Q}(S^*)$ is not.

Definition 4 A probability measure $\mathbb{P}^*$ on $(\Omega, \mathcal{F}_T)$ equivalent to $\mathbb{P}$ (absolutely continuous with respect to $\mathbb{P}$, respectively) is called an equivalent martingale measure for $\mathcal{M} = (S, \Phi)$ (a generalized martingale measure for $\mathcal{M} = (S, \Phi)$, respectively) if for every trading strategy $\phi \in \Phi$ the relative wealth process $V^*(\phi) = V(\phi)B^{-1}$ is a $\mathbb{P}^*$ -martingale with respect to the filtration $\mathbb{F}$.

We write $\mathcal{P}(\mathcal{M})$ ($\mathcal{Q}(\mathcal{M})$, respectively) to denote the class of all equivalent martingale measures (of all generalized martingale measures, respectively) for $\mathcal{M}$. For conciseness, an equivalent martingale measure (a generalized martingale measure, respectively) is abbreviated as EMM (GMM, respectively). Note that an equivalent martingale measure is sometimes referred to as a *risk-neutral probability*.

It can be shown that a trading strategy ϕ is self-financing if and only if the relative wealth process $V^*(\phi) = V(\phi)B^{-1}$ satisfies, for every $t = 0, 1, \dots, T$,

$$V_t^*(\phi) = V_0^*(\phi) + \sum_{u=0}^{t-1} \sum_{i=1}^k \phi_u^i (S_{u+1}^{*i} - S_u^{*i}) \quad (7)$$

Therefore, for any $\phi \in \Phi$ and any GMM $\mathbb{P}^*$ the relative wealth $V^*(\phi)$ is a $\mathbb{P}^*$ -martingale with respect to the filtration $\mathbb{F}$. This leads to the following result.

Lemma 1 A probability measure $\mathbb{P}^*$ on $(\Omega, \mathcal{F}_T)$ is a GMM for the market model $\mathcal{M}$ if and only if it is a GMM for the relative price process S^* , that is, $\mathcal{P}(S^*) = \mathcal{P}(\mathcal{M})$ and $\mathcal{Q}(S^*) = \mathcal{Q}(\mathcal{M})$.

The next result shows that the existence of an EMM for $\mathcal{M}$ is a sufficient condition for the

no-arbitrage property of $\mathcal{M}$. Recall that trivially $\mathcal{P}(\mathcal{M}) \subseteq \mathcal{Q}(\mathcal{M})$ so that the class $\mathcal{Q}(\mathcal{M})$ is manifestly nonempty if $\mathcal{P}(\mathcal{M})$ is so.

Proposition 1 Assume that the class $\mathcal{P}(\mathcal{M})$ is nonempty. Then the market $\mathcal{M}$ is arbitrage free. Moreover, the arbitrage price process of any attainable contingent claim X , which settles at time T , is given by the risk-neutral valuation formula, for every $t = 0, 1, \dots, T$,

$$\pi_t(X) = B_t \mathbb{E}_{\mathbb{P}^*}(X B_T^{-1} | \mathcal{F}_t) \quad (8)$$

where $\mathbb{P}^*$ is any EMM (or GMM) for the market model $\mathcal{M}$.

It can be checked that the binomial tree model (see **Binomial Tree**) with deterministic interest rates is complete, whereas its extension in which the stock price is modeled by a trinomial tree is incomplete. Completeness relies, in particular, on the choice of traded primary assets. Hence, it is natural to ensure completeness of an incomplete model by adding new traded instruments (typically, plain-vanilla options).

Completeness of a Finite Market

We already know that if the set of equivalent martingale measures is nonempty, then the market model $\mathcal{M}$ is arbitrage free. It appears that this condition is also necessary for the no-arbitrage property of the market model $\mathcal{M}$.

Proposition 2 Suppose that the market model $\mathcal{M}$ is arbitrage free. Then the class $\mathcal{P}(\mathcal{M})$ of equivalent martingale measures for $\mathcal{M}$ is nonempty.

This leads to the following version of the *first fundamental theorem of asset pricing* (the *First FTAP*).

Theorem 1 A finite market model $\mathcal{M}$ is arbitrage free if and only if the class $\mathcal{P}(\mathcal{M})$ is nonempty, that is, there exists at least one equivalent martingale measure for $\mathcal{M}$.

In the case of a finite market model, this result was established by Harrison and Pliska [13]. For a probabilistic approach to the First FTAP we refer to Taqqu and Willinger [20], who examine the case of a finite market model, and to papers by Dalang *et al.* [10] and Schachermayer [23], who study the case of a discrete-time model with infinite state space.

The following fundamental result provides a relationship between the completeness property of a finite market model and the uniqueness (or nonuniqueness) of an EMM. Any result of this kind is commonly referred to as the *second fundamental theorem of asset pricing*.

Theorem 2 *Assume that a market model $\mathcal{M}$ is arbitrage free so that the class $\mathcal{P}(\mathcal{M})$ is nonempty. Then $\mathcal{M}$ is complete if and only if the uniqueness of an equivalent martingale measure for $\mathcal{M}$ holds.*

If an arbitrage-free market model is incomplete, not all claims are attainable and the class $\mathcal{P}(\mathcal{M})$ of equivalent martingale measures comprises more than one element. In that case, one can use the following result to determine whether a given contingent claim is attainable.

Corollary 1 *A contingent claim $X \in \mathcal{X}$ is attainable in an arbitrage-free market model $\mathcal{M}$ if and only if the map $\mathbb{P}^* \mapsto \mathbb{E}_{\mathbb{P}^*}(XB_T^{-1})$ from $\mathcal{P}(\mathcal{M})$ to $\mathbb{R}$ is constant.*

It follows from this result that if a claim is attainable, so that its arbitrage price is well defined, the price can be computed using the risk-neutral valuation formula under any of (possibly several) martingale measures. In addition, if the risk-neutral valuation formula yields the same result for any choice of an EMM for the market model at hand, then a given claim is necessarily attainable.

Multidimensional Black and Scholes Model

A multidimensional Black and Scholes model is a natural extension to a multiasset setup of the classic Black and Scholes [3] options pricing model. Let k denote the number of primary risky assets. For any $i = 1, \dots, k$, the price process S^i of the i th risky asset, referred to as the i th stock, is modeled as an Itô process (the dot $\cdot$ stands for the inner product in $\mathbb{R}^d$)

$$dS_t^i = S_t^i(\mu_t^i dt + \sigma_t^i \cdot dW_t) \quad (9)$$

with $S_0^i > 0$ or, more explicitly,

$$dS_t^i = S_t^i \left(\mu_t^i dt + \sum_{j=1}^d \sigma_t^{ij} dW_t^j \right) \quad (10)$$

where $W = (W^1, \dots, W^d)$ is a standard d -dimensional Brownian motion, defined on a filtered probability space $(\Omega, \mathbb{F}, \mathbb{P})$. We make the natural assumption that the underlying filtration $\mathbb{F}$ coincides with the filtration $\mathbb{F}^W$ generated by the Brownian motion W . The coefficients μ^i and σ^i follow bounded progressively measurable processes on the space $(\Omega, \mathbb{F}, \mathbb{P})$, with values in $\mathbb{R}$ and $\mathbb{R}^d$, respectively. An important special case is obtained by postulating that for every i the volatility coefficient σ^i is represented by a fixed vector in $\mathbb{R}^d$ and the appreciation rate μ^i is a real number.

For brevity, we write $\sigma = \sigma_t$ to denote the volatility matrix—that is, the time-dependent random matrix $[\sigma_t^{ij}]$, whose i th row specifies the volatility of the i th traded stock. The last primary security is the risk-free savings account B with the price process $S^{k+1} = B$ satisfying

$$dB_t = r_t B_t dt, \quad B_0 = 1 \quad (11)$$

for a bounded, nonnegative, progressively measurable interest rate process r . This means that, for every $t \in [0, T]$,

$$B_t = \exp \left(\int_0^t r_u du \right) \quad (12)$$

To ensure the absence of arbitrage opportunities, we postulate the existence of a d -dimensional, progressively measurable process γ such that the equality

$$r_t - \mu_t^i = \sum_{j=1}^d \sigma_t^{ij} \gamma_t^j = \sigma_t^i \cdot \gamma_t \quad (13)$$

is satisfied simultaneously for every $i = 1, \dots, k$ (for Lebesgue a.e. $t \in [0, T]$, with probability one). Note that the *market price for risk* γ is not uniquely determined, in general. Indeed, the uniqueness of a solution γ to this equation holds only if $d \leq k$ and the volatility matrix σ has the full rank for every $t \in [0, T]$.

For example, if $d = k$ and the volatility matrix σ is nonsingular (for Lebesgue a.e. $t \in [0, T]$, with probability one), then, for every $t \in [0, T]$,

$$\gamma_t = \sigma_t^{-1}(r_t \mathbf{1} - \mu_t) \quad (14)$$

where $\mathbf{1}$ denotes the d -dimensional vector with every component equal to one, and μ_t is the vector with components μ_t^i . For any process γ satisfying the

above equation, we introduce a probability measure $\mathbb{P}^*$ on $(\Omega, \mathcal{F}_T)$ by setting

$$\frac{d\mathbb{P}^*}{d\mathbb{P}} = \exp \left(\int_0^T \gamma_u \cdot dW_u - \frac{1}{2} \int_0^T \|\gamma_u\|^2 du \right), \quad \mathbb{P}\text{-a.s.} \quad (15)$$

provided that the right-hand side in the last formula is well defined. The Doléans (stochastic) exponential

$$\eta_t = \exp \left(\int_0^t \gamma_u \cdot dW_u - \frac{1}{2} \int_0^t \|\gamma_u\|^2 du \right) \quad (16)$$

is known to be a strictly positive supermartingale (but not necessarily a martingale) under $\mathbb{P}$, since it may happen that $\mathbb{E}_{\mathbb{P}^*}(\eta_T) < 1$. A probability measure $\mathbb{P}^*$ equivalent to $\mathbb{P}$ is well defined if and only if the process η follows a $\mathbb{P}$ -martingale, that is, when $\mathbb{E}_{\mathbb{P}^*}(\eta_T) = 1$. For the last property to hold, it is enough (but not necessary) that γ is a bounded process.

Assume that the class of martingale measures is nonempty. By virtue of the Girsanov theorem, the process W^* , which equals, for every $t \in [0, T]$,

$$W_t^* = W_t - \int_0^t \gamma_u du \quad (17)$$

is a d -dimensional standard Brownian motion on $(\Omega, \mathbb{F}, \mathbb{P}^*)$. It follows from the Itô formula that the discounted stock price $S_t^{*i} = S_t^i B_t^{-1}$ satisfies under $\mathbb{P}^*$

$$dS_t^{*i} = S_t^{*i} \sigma_t^i \cdot dW_t^* \quad (18)$$

for any $i = 1, \dots, k$. This means that the discounted prices of all stocks follow local martingales under $\mathbb{P}^*$, so that any probability measure described above is a martingale measure for our model and it corresponds to the choice of the savings account as the *numéraire asset*. The class of *tame strategies* relative to B is defined by postulating that the discounted wealth of a strategy follows a stochastic process bounded from below. The market model obtained in this way is referred to as the *multidimensional Black and Scholes model*.

In the classic version of the multidimensional Black and Scholes model, one postulates that $d = k$, the constant volatility matrix σ is nonsingular, and the appreciation rates μ_i and the continuously compounded interest rate r are constant. It is easily

seen that under these assumptions, the martingale measure $\mathbb{P}^*$ exists and is unique.

Completeness of the Multidimensional Black and Scholes Model

The completeness of the multidimensional Black and Scholes model is defined in much the same way as for a finite market model, except that certain technical restrictions need to be imposed on the class of contingent claims we wish to hedge and price. This is linked to the fact that not all self-financing trading strategies are deemed to be *admissible*. Some of them should be excluded in order to ensure the no-arbitrage property of the model (in addition to the existence of a martingale measure). Typically, one considers the class of tame strategies to play the role of admissible trading strategies.

The multidimensional Black and Scholes model is said to be *complete* if any $\mathbb{P}^*$ -integrable, bounded from below contingent claim X is attainable, that is, if for any such claim X there exists an admissible trading strategy ϕ such that $X = V_T(\phi)$. Otherwise, the market model is said to be *incomplete*.

Since, by assumption, the interest rate process r is nonnegative and bounded, the integrability and boundedness of X is therefore equivalent to the integrability and boundedness of the discounted claim X/B_T . It is not postulated that the uniqueness of an EMM holds, and thus the $\mathbb{P}^*$ -integrability of X refers to any EMM for the model. The next result establishes necessary and sufficient conditions for the completeness of the Black and Scholes market.

Proposition 3 *The following are equivalent:*

1. *the multidimensional Black and Scholes model is complete;*
2. *inequality $d \leq k$ holds and the volatility matrix σ has full rank for Lebesgue a.e. $t \in [0, T]$, with probability 1;*
3. *there exists a unique equivalent martingale measure $\mathbb{P}^*$ for discounted stock price S^{*i} for every $i = 1, \dots, k$.*

The classic one-dimensional Black and Scholes market model introduced in [3] is clearly a special case of the multidimensional Black and Scholes model. Hence, the above results apply also to the classic Black and Scholes market model, in which the

martingale measure $\mathbb{P}^*$ is well known to be unique. We conclude that the one-dimensional Black and Scholes market model is complete, that is, any $\mathbb{P}^*$ -integrable contingent claim is $\mathbb{P}^*$ -attainable and thus it can be priced by arbitrage.

In the general semimartingale framework, the equivalence of the uniqueness of an EMM and the completeness of a market model were conjectured by Harrison and Pliska [13, 14] (see also [18]). The case of the Brownian filtration is examined in [16]. Chatelain and Stricker [7, 8] provide definitive results for the case of continuous local martingales (see also [1, 20] for related results). They focus on the important distinction between the vector and componentwise stochastic integrals.

Local and Stochastic Volatility Models

Note that we have examined the completeness of the market model in which trading was restricted to a predetermined family of primary securities. In practice, several derivative securities are also traded either on organized exchanges or over-the-counter and thus they can be used to formally complete a given market model. Let us comment briefly on two classes of models in which, for simplicity, we assume that the bond price is deterministic.

Following Dupire [12], we define the stock price as a solution to the following stochastic differential equation:

$$dS_t = S_t(\mu(S_t, t) dt + \sigma(S_t, t) dW_t^*) \quad (19)$$

where $S_0 > 0$ and the function $\sigma : \mathbb{R}_+ \times \mathbb{R}_+ \rightarrow \mathbb{R}$ represents the so-called local volatility. In practice, the function σ is obtained by fitting the model to market quotes of traded options. Model of this form is complete and thus any derivative security with the stock price as an underlying asset can be hedged and priced by arbitrage (provided, of course, that the model is arbitrage free). Another example of a complete model in which the volatility follows a stochastic process is discussed by Hobson and Rogers [15].

In a typical stochastic volatility model, the stock price S is governed by the equation

$$dS_t = \mu(S_t, t) dt + \sigma_t S_t dW_t \quad (20)$$

where the *stochastic volatility* process σ satisfies

$$d\sigma_t = a(\sigma_t, t) dt + b(\sigma_t, t) d\widehat{W}_t \quad (21)$$

where W and $\widehat{W}$ are (possibly correlated) one-dimensional Brownian motions defined on some filtered probability space $(\Omega, \mathbb{F}, \mathbb{P})$. Owing to the presence of the Brownian motion $\widehat{W}$, stochastic volatility models are incomplete if stock and bond are the only trade primary assets. By postulating that some plain-vanilla options are traded, it is possible to complete a stochastic volatility model, however. Completeness of a model of financial market with traded call and put options and related topics, such as *static hedging* of exotic options, was examined by several authors: Bajeux-Besnainou and Rochet [2], Breeden and Litzenberger [4], Brown *et al.* [5], Carr *et al.* [6], Derman *et al.* [11], Madan and Milne [17], Nachman [19], Romano and Touzi [21], and Ross [22], to mention a few.

Equivalent Martingale Measures

The usual setting of mathematical finance is provided by a d -dimensional stochastic process $S = (S_t)_{0 \leq t \leq T}$ based on and adapted to a filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$. This process S models the price evolution of d risky stocks, which is random.

To alleviate notation, we assume from the very beginning that these prices are denoted in discounted terms: fix a traded asset, the “bond”, as numéraire and express stock prices S in units of this bond. This simple and classical technique allows us to dispense with discount factors in the formulae below (compare Section 2.1 in [6] for more details).

A central topic in mathematical finance is to decide whether there is a probability measure Q , equivalent to $\mathbb{P}$, such that S is a martingale under Q . This is the theme of the fundamental theorem of asset pricing (*see Fundamental Theorem of Asset Pricing*). Once we know that there exist equivalent martingale measures, they can be used to determine risk-neutral prices of derivative securities by taking expectations under these measures (*see Risk-neutral Pricing*), and to replicate, respectively, sub- or superreplicate, the derivative.

In fact, we were less precise in the previous paragraph (as is usual in this context) by requiring that S is a *martingale*. It turns out that some technical care is needed here, involving the notions of *local martingales* and, more generally, of *sigma-martingales*. This article deals precisely with these technical variants of the concept of a martingale.

We start by giving precise definitions.

Definition 1 An $\mathbb{R}^d$ -valued stochastic process $(S_t)_{0 \leq t \leq T}$ based on and adapted to $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$ is called a

(i) *martingale* if

$$\mathbb{E}[S_t | \mathcal{F}_u] = S_u, \quad 0 \leq u \leq t \leq T \quad (1)$$

(ii) *local martingale* if there exists a sequence $(\tau_n)_{n=1}^\infty$ of $[0, T] \cup \{+\infty\}$ -valued stopping times, increasing a.s. to ∞ , such that the stopped processes $S_{t \wedge \tau_n}$ are all martingales, where

$$S_{t \wedge \tau_n} = S_t, \quad 0 \leq t \leq T \quad (2)$$

(iii) *sigma-martingale* if there is an $\mathbb{R}^d$ -valued martingale $M = (M_t)_{0 \leq t \leq T}$ and a predictable M -integrable $\mathbb{R}_+$ -valued process φ such that $S = \varphi \cdot M$.

The process $\varphi \cdot M$ is defined as the stochastic integral in the sense of semimartingales. The—by now well understood—underlying theory was developed notably by the school of P.A. Meyer in Strasbourg [10–12]:

$$(\varphi \cdot M)_t = \int_0^t \varphi_u dM_u, \quad 0 \leq t \leq T \quad (3)$$

It is not obvious, but true, that a local martingale is a sigma-martingale, so that (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) holds true above, while the reverse implications fail to hold true as we discuss later.

Why is it necessary to introduce these generalizations of the concept of a martingale? Let us start with a familiar example of a martingale, namely, geometric Brownian motion

$$M_t = \exp \left[W_t - \frac{t}{2} \right], \quad t \geq 0 \quad (4)$$

where the process $(W_t)_{t \geq 0}$ is a standard Brownian motion.

Clearly, $(M_t)_{t \geq 0}$ is a martingale (with reference to its natural filtration) when t ranges in $[0, \infty[$. But what happens if we include $t = \infty$ into the time set? It is straightforward to verify that

$$M_\infty := \lim_{t \rightarrow \infty} M_t \quad (5)$$

exists a.s. and equals

$$M_\infty = 0 \quad (6)$$

Hence we may well define the continuous process $(M_t)_{0 \leq t \leq \infty}$; this process is not a martingale any more as

$$1 = M_0 > \mathbb{E}[M_\infty] = 0 \quad (7)$$

In this example, the breakdown of the martingale property happens at $t = \infty$. However, it is purely formal to shift this problem to any other point $T \in]0, \infty[$, for example, $T = 1$. Indeed, letting

$$\begin{aligned} \tilde{M}_t &= M_{\tan(\frac{t\pi}{2})}, \quad 0 \leq t < 1 \\ \tilde{M}_1 &= M_\infty = 0 \end{aligned} \quad (8)$$

we find a process $(\tilde{M}_t)_{0 \leq t \leq 1}$, having a.s. continuous paths, which fails to be a martingale. However, it is intuitively clear that “locally”, that is, before t assumes the value 1, the process $(\tilde{M}_t)_{0 \leq t \leq 1}$ is “something like a martingale”. The good way to formalize this intuition is to find a “localizing” sequence of stopping times as in (ii) above. The canonical choice^a is

$$\tau_n = \inf\{t \in [0, 1] : |\tilde{M}_t| \geq n\} \quad (9)$$

which is a $[0, 1] \cup \{\infty\}$ -valued stopping time, if we define the infimum over the empty set to be equal to ∞ . It is straightforward to verify that $(\tau_n)_{n=1}^\infty$ satisfies the requirements of (ii) above.

In the above example it holds true that $(\tilde{M}_t)_{0 \leq t < 1}$ is a martingale, that is, when t ranges in $[0, 1[$. In other words, the problem only arises at $t = 1$. However, there is a more subtle phenomenon in this context, where the problem not only appears at one single value of t , but also for *all* t .

The canonical example for this phenomenon is the inverse of the three-dimensional Bessel process^b $(R_t)_{0 \leq t \leq 1}$. It may be defined by $R_0 = 1$ and

$$dR_t = R_t^2 dW_t, \quad 0 \leq t \leq 1 \quad (10)$$

It turns out that equation (10) well defines a stochastic process with continuous paths, which is a local martingale (define $(\tau_n)_{n=1}^\infty$ as in equation (9)). However, the function

$$t \rightarrow \mathbb{E}[R_t], \quad 0 \leq t \leq 1 \quad (11)$$

is *strictly decreasing* on the entire interval $[0, 1]$. Intuitively speaking, this may be interpreted as $(R_t)_{0 \leq t \leq 1}$ “losing mass in continuous time”. We leave it to the reader to develop his or her own intuition for this remarkable phenomenon. In any case, this example should convince the reader that the concept of *local martingales*, involving “localizing” sequences of stopping times, is a useful and natural notion.

To underline this claim even further, think of a diffusion process $(X_t)_{0 \leq t \leq 1}$ satisfying the equation

$$dX_t = \sigma(X_t, t) dW_t + \mu(X_t, t) dt, \quad 0 \leq t \leq 1 \quad (12)$$

A typical argument used, for example, in the derivation of the Black–Scholes partial differential equation (PDE) (compare **Complete Markets**

or [Vol. II] [13]), goes as follows: for the drift term $\mu(X_t, t)$ we have $\mu(X_t, t) \equiv 0$ if and only if $(X_t)_{0 \leq t \leq 1}$ is a martingale. This is a very useful argument. However, this argument is not quite complete, as a glance at equation (10) reveals where we only obtain a local martingale. The correct statement is the process X is a *local martingale* if and only if $\mu(X_t, t) = 0$, a.s. with respect to $d\mathbb{P} \otimes d\lambda$.

Local Martingales in Finance

As a concrete example of a local martingale modeling a price process we consider $\tilde{S} = (\tilde{S}_t)_{0 \leq t \leq T} = (\tilde{M}_t)_{0 \leq t \leq 1}$, the time-changed geometric Brownian motion defined in equation (8). We consider $\tilde{S}$ to be defined on $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$, where the filtration $(\mathcal{F}_t)_{0 \leq t \leq T}$ is generated by $\tilde{S}$ and $\mathcal{F} = \mathcal{F}_T$. We conclude that $Q = \mathbb{P}$ is the unique probability measure Q on $\mathcal{F}$, which is equivalent to $\mathbb{P}$ and such that $\tilde{S}$ is a local martingale under Q . This quickly follows from the fact that $Q = \mathbb{P}$ is the unique probability measure on $\mathcal{F}$, equivalent to $\mathbb{P}$, such that the Brownian motion $W = (W_t)_{0 \leq t < \infty}$ in equation (4) is a martingale under Q .

The question arises whether $\tilde{S}$ defines a sound, that is, arbitrage-free model of a financial market. At first glance, things seem suspicious; after all, $(\tilde{S}_t)_{0 \leq t \leq T}$ is a ridiculous stock; it starts at $\tilde{S}_0 = 1$ and ends a.s. at $\tilde{S}_T = 0$. Hence buying a stock $\tilde{S}$ and holding it up to time $T = 1$ is a very “silly investment”. M. Harrison and St. Pliska [8] called such an investment a *suicide strategy*. But it is not forbidden to be silly.

A much more appealing investment strategy would be to go short in the stock at time 0, and to hold this short position up to time T , as this strategy yields a.s. a gain of one Euro. However, unfortunately, this is forbidden. To understand why this is the case, let us recall from **Fundamental Theorem of Asset Pricing** the definition of *admissibility*: a trading strategy $H = (H_t)_{0 \leq t \leq T}$ for a (general semimartingale) stock price process S is defined as a predictable strategy, which is S -integrable. By definition, the stochastic integral

$$(H \cdot S)_t = \int_0^t (H_u, dS_u), \quad 0 \leq t \leq T \quad (13)$$

then is well defined. We call H *admissible*, if there is a constant $C > 0$ such that a.s.

$$(H \cdot S)_t \geq -C, \quad 0 \leq t \leq T \quad (14)$$

The finite credit line C rules out doubling strategies and similar schemes that capitalize on taking higher and higher risks. A typical representative of such a “kind of doubling strategy” is the strategy of going short in the stock $(\tilde{S}_t)_{0 \leq t \leq T}$, which corresponds to taking $H_t \equiv -1$, for $0 \leq t \leq T$.

We now shall convince ourselves that local martingales yield sound, arbitrage-free models of financial markets. It turns out that it does not matter whether we start with a true martingale $S = (S_t)_{0 \leq t \leq T}$ or with a local martingale S , if we are only interested in the *admissible stochastic integrals* $H \cdot S$. Indeed, it was shown by J.P. Ansel and C. Stricker [1, Corr. 3.5] that, given a local martingale S and an admissible integrand H , the stochastic integral $H \cdot S$ is a local martingale and therefore (using once more the fact that $H \cdot S$ is bounded from below) a supermartingale. In particular, the process $H \cdot S$ cannot increase in expectation; but it may very well decrease in expectation as, for example, the process $\tilde{S}$ above.

The following characterization of local martingales (see [4, Prop. 2.5] for more on this issue) is useful in this context.

Proposition 1 *For an $\mathbb{R}^d$ -valued semimartingale S the following are equivalent.*

- (i) S is a local martingale.
- (ii) $S = \varphi \cdot M$, where M is an $\mathbb{R}^d$ -valued martingale, and φ is an $\mathbb{R}_+$ -valued, M -integrable, predictable, increasing process.

From this proposition and the trivial formula^c

$$H \cdot M = \frac{H}{\varphi} \cdot (\varphi \cdot M) = \frac{H}{\varphi} \cdot S \quad (15)$$

which holds true for every $\mathbb{R}^d$ -valued, predictable, M -integrable process $H = (H_t)_{0 \leq t \leq T}$ we deduce that the family of processes, which are stochastic integrals on the local martingale S coincides with the family of processes, which are stochastic processes on the martingale M . Also note that H is admissible for M if and only if $\frac{H}{\varphi}$ is admissible for S .

The bottom line of formula (15) is that *there is no difference between the stock price process S and M in Proposition 1* if we are only interested in the *admissible stochastic integrals* on these processes: these two families of stochastic integrals coincide.

Sigma-martingales

For continuous stock price processes S or, more generally, for locally bounded processes S , the concept of *local martingales* is sufficiently general to characterize those models that satisfy the condition of *no free lunch with vanishing risk* (see **Fundamental Theorem of Asset Pricing**).

However, if we pass to processes S that are not locally bounded any more, we still need one more step of generalization. The key concept for doing so was introduced by C. Chou [2] and M. Émery [7] under the name of “semimartingale de la classe (Σ_m) ”. In [4], F. Delbaen and this author took the liberty of calling these processes *sigma-martingales* S . The reason for this is that their relation to martingales is analogous to the relation between sigma-finite measures and finite measures, as seen from Definition 1 above. Also note the (only) difference between Definition 1 (iii) of a sigma-martingale, and the characterization of a local martingale as given in Proposition 1: in the latter the predictable, $\mathbb{R}_+$ -valued process φ is supposed to be *increasing* while there is no such restriction in the former one.

Here is the illuminating example, due to M. Émery [7] (compare [4, Ex. 2.2]), of the archetypical sigma-martingale, which fails to be a local martingale.

Example 1 We start with an exponentially distributed random variable τ and an independent Bernoulli random variable ε , that is, $\mathbb{P}[\varepsilon = 1] = \mathbb{P}[\varepsilon = -1] = \frac{1}{2}$. These random variables are based on some probability space $(\Omega, \mathcal{F}, \mathbb{P})$.

Define the process $M = (M_t)_{t \geq 0}$ by

$$M_t = \begin{cases} 0, & \text{for } 0 \leq t \leq \tau \\ \varepsilon, & \text{for } \tau \leq t \end{cases} \quad (16)$$

The verbal description goes like this: the process M remains at zero until time τ ; then a coin is flipped, independently of τ , and the process M continues at the level $+1$ or -1 , according to the result of this coin flip.

Denoting by $(\mathcal{F}_t)_{t \geq 0}$ the filtration generated by $(M_t)_{t \geq 0}$, it is rather obvious that $(M_t)_{t \geq 0}$ is a *martingale* in this filtration $(\mathcal{F}_t)_{t \geq 0}$. To keep in line with the above notation, we only consider the finite-horizon process $(M_t)_{0 \leq t \leq T}$, but the example could as well be presented for the infinite horizon.

Let $\varphi = (\varphi_t)_{0 \leq t \leq 1}$ be the *deterministic process*

$$\varphi_t = t^{-1}, \quad 0 \leq t \leq 1 \quad (17)$$

and define the stochastic integral $S = \varphi \cdot M$, for which we get

$$S_t = \begin{cases} 0, & \text{for } 0 \leq t \leq \tau \\ \tau^{-1}\varepsilon, & \text{for } \tau \leq t \end{cases} \quad (18)$$

The process $S = (S_t)_{0 \leq t \leq 1}$ is a well-defined stochastic integral (in the pointwise Stieltjes sense). The verbal description of S goes as follows: again S remains at 0 until time τ and then, depending on the sign of ε , it jumps to $+\tau^{-1}$ or $-\tau^{-1}$.

Is the process S a martingale? Morally speaking, one might think yes, as it has the same odds of jumping up or down.^d But this intuition goes wrong: indeed, the notion of martingale is based on some (conditional) expectations to be zero. When we do the calculations in the present example we end up with expressions of the form $\infty - \infty$, which creates a problem. Indeed, we have

$$\mathbb{E}[|S_t|] = \infty, \quad \text{for } 0 \leq t \leq 1 \quad (19)$$

as is easily seen from $\int_0^t u^{-1} du = \infty$, for $t > 0$. In fact, it is not hard to show [7] that, for every $(\mathcal{F}_t)_{0 \leq t \leq 1}$ —stopping time $\sigma : \Omega \rightarrow [0, 1]$, such that $\mathbb{P}[\sigma > 0] > 0$, we have

$$\mathbb{E}[|S_\sigma|] = \infty \quad (20)$$

It follows that S even *fails to be a local martingale*. But, of course, S is a sigma-martingale by its very construction.

The message of the above example is that the notion of sigma-martingale is tailor-made to save the intuition that—from a “moral point of view”—the above process S is “something like a martingale”.

Let us turn from moral considerations to finance again: the question arises as to whether a process $S = (S_t)_{0 \leq t \leq T}$, which is a sigma-martingale under some measure Q equivalent to $\mathbb{P}$, well defines a sound, that is, arbitrage-free, model of a financial market. The answer is analogous to the case of a local martingale, namely, a resounding *yes*. If $S = \varphi \cdot M$, for some $\mathbb{R}_+$ -valued predictable process φ , then again the “trivial formula” (15) above holds true. Hence again the families of *admissible stochastic integrals* on the processes S and M coincide. If these are the only relevant objects—as is the case for the classical approach to no-arbitrage theory as proposed by M. Harrison and S. Pliska [8]—the

processes S and M work equally well. In particular, the Ansel–Stricker Theorem carries over to sigma-martingales (see [4, Th. 5.5] for a somewhat stronger version of this result).

It is not hard to show that a locally bounded process, which is a sigma-martingale, is already a local martingale [4, Prop. 2.5 and 2.6]. Émery’s example shows that this is not the case any more if we drop the local boundedness assumption. From a financial point of view, however, the question of interest arises in a slightly different version. Is there an example of a process $S = (S_t)_{0 \leq t \leq T}$, which is a sigma-martingale, say under $\mathbb{P}$, but such that it *fails to be a local martingale under any probability measure Q equivalent to $\mathbb{P}$* ?

Émery’s original example does not provide a counterexample to this question; in this example, it is not hard to pass from $\mathbb{P}$ to Q such that S even becomes a Q -martingale. However, in [4, Ex. 2.3] a variant of Émery’s example has been constructed, which is a process S taking values in $\mathbb{R}^2$ answering the above question negatively. It seems worth mentioning that—to the best of the author’s knowledge—it is unknown whether there also is a counterexample of a process S , taking values only in $\mathbb{R}$, to this question.

Separating Measures

We have seen in the preceding sections that, for a process $S = (S_t)_{0 \leq t \leq T}$ which is a sigma-martingale under some probability measure Q and for each admissible integrand H , we have the inequality

$$\mathbb{E}_Q[(H \cdot S)_T] \leq 0 \quad (21)$$

Indeed, the theorem of Ansel–Stricker [1, Corr. 3.5] and its extension to sigma-martingales [4, Th. 5.5] imply that $H \cdot S$ is a local martingale and, using again the boundedness from below, the process $H \cdot S$ is a supermartingale.

The notion of a *separating measure* introduced by Y. Kabanov in [9], takes this inequality (21) as defining property. To formalize this idea, we assume that S is an $\mathbb{R}^d$ -valued semimartingale on some filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{0 \leq t \leq T}, \mathbb{P})$. We say that a measure Q , equivalent to $\mathbb{P}$, is a *separating measure* for S if, for all admissible, predictable S -integrable integrands H , inequality (21) holds true.

If S is bounded, then it is straightforward to verify that the validity of inequality (21), for all admissible H , is tantamount to S being a martingale. It follows that, if S is locally bounded, then the validity of inequality (21), for all admissible H , is tantamount to S being a local martingale. Hence, we do not find anything new by using the notion of *separating measure* in the context of locally bounded semimartingales S . However, for semimartingales S that are not locally bounded, we do find something new; as observed above, if S is a sigma-martingale under Q then inequality (21) holds true, for all admissible H . But the converse does not hold true. The difference is illustrated by the subsequent easy one-period example. To stay in line with the present notation, we write it as an example in continuous time.

Example 2 Let X be an $\mathbb{R}$ -valued random variable, defined on some probability space $(\Omega, \mathcal{F}, \mathbb{P})$, which is unbounded from above and from below. For example, we may choose X to be normally distributed.

The process $S = (S_t)_{0 \leq t \leq 1}$ is defined as

$$S_t = \begin{cases} 0 & 0 \leq t < 1 \\ X & t = 1 \end{cases} \quad (22)$$

Defining $(\mathcal{F}_t)_{0 \leq t \leq 1}$ as the filtration generated by $S = (S_t)_{0 \leq t \leq 1}$, we find that the only $(\mathcal{F}_t)_{0 \leq t \leq 1}$ -predictable processes are the *constant processes* $H = (H_t)_{0 \leq t \leq 1}$. Among those, the only S -admissible predictable process is $H = 0$. Indeed, if $H = \text{const} \neq 0$, the process $H \cdot S$ is not bounded from below in the sense of inequality (14).

The condition (21) therefore is trivially satisfied, for *each* probability measure Q equivalent to $\mathbb{P}$. On the other hand, S is a martingale (or, equivalently, a local or a sigma-martingale) under Q if

$$\mathbb{E}_Q[X] = \mathbb{E}_Q[S_1] = 0 \quad (23)$$

Hence we see that, in this easy example, the class of separating measures Q is strictly bigger than the class of probability measures Q , equivalent to $\mathbb{P}$, under which S is a sigma-martingale.

Where does the nomenclature “separating measure” come from? This concept arises naturally as an intermediary step in the proof of **Fundamental Theorem of Asset Pricing** (compare [9] for a careful analysis of the arguments in [3] and [4] and, in particular, for the introduction of the name “separating measure”).

In the context of this theorem, after surmounting some difficulties, an application of the Hahn–Banach theorem plus an exhaustion argument due to J. Yan ([15], compare also [14]) provides a σ^* -continuous, linear functional $F : L^\infty(\Omega, \mathcal{F}, \mathbb{P}) \rightarrow \mathbb{R}$ which *strictly separates* the set of random variables of the form^e

$$(H \cdot S)_T = \int_0^T (H_t, dS_t) \quad (24)$$

where H runs through the admissible integrands, from $L_+^\infty(\Omega, \mathcal{F}, \mathbb{P}) \setminus \{0\}$, that is, the positive orthant with the origin 0 deleted. Normalizing the functional F by $F(\zeta) = 1$, this translates into the fact that F is of the form

$$F(g) = \mathbb{E}_Q[g], \quad g \in L^\infty(\Omega, \mathcal{F}, \mathbb{P}) \quad (25)$$

where Q is a *separating measure*.

If the process S is bounded (respectively, locally bounded), it immediately follows that S is a martingale (respectively, a local martingale) under this separating measure Q , which concludes the proof of the fundamental theorem of asset pricing (see [3]).

If, however, S fails to be locally bounded, then we cannot conclude that S is “some kind of martingale” under the separating measure Q , as is illustrated by Example 2 above. Some further work is needed—which was carried out in [4]—to pass from the separating measure Q to a probability measure $\tilde{Q}$, which is equivalent to $\mathbb{P}$ and under which S is a sigma-martingale measure. It turns out that, in the setting of the fundamental theorem of asset pricing [4], the latter set is dense with reference to $\|\cdot\|_1$ in the set of separating measures for S . In particular, this set is nonempty, provided we have found a separating measure. This argument concludes the proof of the fundamental theorem of asset pricing also in the case of a general, $\mathbb{R}^d$ -valued semimartingale S .

End Notes

^aFor *continuous* local martingales $(M_t)_{t \geq 0}$ starting at $M_0 = 0$ the choice of stopping times *via* equation (9) always works, that is, gives a sequence $(\tau_n)_{n=1}^\infty$ satisfying the requirements of (ii) above. In the case of càdlàg local martingales this is not true any more and one may give examples of local martingales where equation (9) does not define a sequence of localizing stopping times.

^bThe name is derived from the following fact: let $(B_t)_{0 \leq t \leq 1} = (B_t^1, B_t^2, B_t^3)_{0 \leq t \leq 1}$ be an $\mathbb{R}^3$ -valued standard Brownian motion starting at $B_0 = (B_0^1, B_0^2, B_0^3) = (1, 0, 0)$. Let $R_t = \|B_t\|^{-1}$ where $\|\cdot\|$ denotes Euclidean norm on $\mathbb{R}^3$. Then $(R_t)_{0 \leq t \leq 1}$ satisfies equation (10), where $(W_t)_{0 \leq t \leq 1}$ is a one-dimensional Brownian motion adapted to the filtration generated by the three-dimensional Brownian $(B_t)_{0 \leq t \leq 1}$. We refer to [11] for a beautiful presentation of the theory of Bessel processes (compare also [5]).

^cIt is easy to verify that in Proposition 1 (as well as in Definition 1 (iii)), we may assume without loss of generality that φ takes its values in $]0, \infty[$ (or, equivalently, in $[1, \infty[$). See [4, Prop. 2.5] for details.

^dA precise statement is that the processes S and $-S$ have the same law, which obviously is the case.

^eTo be precise, we have to consider the random variables $(H \cdot S)_T \wedge C$, where C runs through $\mathbb{R}_+$, to make sure that these random variables are in $L^\infty(\Omega, \mathcal{F}, \mathbb{P})$.

Second Fundamental Theorem of Asset Pricing

The *second fundamental theorem of asset pricing* concerns the mathematical characterization of the economic concept of *market completeness* for liquid and frictionless markets with an arbitrary number of assets. The theorem establishes the mathematical necessary and sufficient conditions in order to guarantee that every contingent claim on the market can be duplicated with a portfolio of primitive assets. For finite asset economies, completeness (i.e., *perfect replication* of every claim on the market by admissible self-financing strategies) is equivalent to uniqueness of the equivalent martingale measure. This result can be extended to market models with an infinite number of assets by defining completeness in terms of *approximate replication* of claims by attainable ones. Hence several definitions of completeness are possible, and in the sequel we will present and discuss them extensively.

Finite Number of Assets

The *second fundamental theorem* appeared in [9] under the assumption that the interest rate is zero and that the agent employs only simple trading strategies to address the following issue, raised in the economic literature [1, 20, 22]: given a financial market, which contingent claims are “spanned” by a given set of market securities?

In the seminal paper [7], it was already observed that in the idealized Black–Scholes market the cash flow of an option can be duplicated by managing a portfolio containing only stock and bond. A natural question is then as follows: for which contingent claim does this result hold in more general markets? When does it hold for *all* contingent claims on the market?

For markets with a finite number of asset prices, the answer to this problem was provided for the first time in [10, 11]. Here we follow the notation of [11] in order to state the *second fundamental theorem*.

Let $T < \infty$ be a fixed time horizon; consider a probability space $(\Omega, \mathcal{F}, P)$ endowed with a filtration $(\mathcal{F}_t)_{t \in [0, T]}$ satisfying the usual conditions and such that $\mathcal{F}_0$ contains only Ω and the null sets of P

and with $\mathcal{F}_T = \mathcal{F}$. Let $S = (S_t^0, \dots, S_t^d)_{t \in [0, T]}$ be a $(d + 1)$ -dimensional strictly positive semimartingale, whose components $S^0, \dots, S^d$ are right continuous with left limits. Moreover, we assume that $S_0^0 = 1$. Here, the stochastic process S_t^k represents the value at time t of the k th security on the market. The discounted price process $Z = (Z_t^1, \dots, Z_t^d)_{t \in [0, T]}$ is then defined by setting $Z^k = S^k/S^0$, for $k = 1, \dots, d$. Let $\mathbb{P}$ be the set of probability measures Q on $(\Omega, \mathcal{F})$ that are equivalent to P and such that Z is a (vector) martingale under Q . We assume that $\mathbb{P}$ is not empty, that is, that the market is arbitrage free (see **Fundamental Theorem of Asset Pricing**). We fix an element P^* in $\mathbb{P}$ and denote by E^* the expectation under P^* . Let $L(Z)$ denote the set of all vector-valued, predictable processes $H = (H_t^1, \dots, H_t^d)_{t \in [0, T]}$ that are *integrable* with respect to the semimartingale Z . For further details on $L(Z)$, we refer to Remark 1 below.

Definition 1 A stochastic process $\phi \in L(Z)$ is said to be an *admissible self-financing strategy* if

- (i) the discounted value process $V^*(\phi) := \sum_{k=1}^d \phi^k Z^k$ is almost surely nonnegative;
- (ii) $V^*(\phi)$ satisfies the self-financing condition

$$V_t^*(\phi) = V_0^*(H) + \int_0^t \sum_{k=1}^d \phi_s^k dZ_s^k, \quad t \in [0, T]; \quad (1)$$

- (iii) $V^*(\phi)$ is a martingale under P^* .

Condition (iii) is introduced here to rule out “certain foolish strategies that throw out money” [11], that is, for no-arbitrage reasons. Note also that in the preceding definition only the last condition may depend on the choice of the reference measure P^* .

A *contingent claim* X with maturity T is then represented by a nonnegative $(\mathcal{F}_T$ -measurable) random variable. Such a claim is said to be *attainable* if there exists an admissible trading strategy ϕ such that $V_T^*(\phi) = X/S_T^0$. The model is said to be *complete* if every claim^a is attainable.

Theorem 1 (The second fundamental theorem of asset pricing, [11]). *Let $\mathbb{P} \neq \emptyset$. Then the following statements are equivalent:*

- (i) The model is complete under P^* .

- (ii) Every P^* -martingale M can be represented in the form

$$M_t = M_0 + \int_0^t \sum_{k=1}^d H_s^k dZ_s^k, \quad t \in [0, T] \quad (2)$$

for some $H \in L(Z)$ (predictable representation property).

- (iii) $\mathbb{P}$ is a singleton, that is, there exists a unique equivalent martingale measure for Z .

The proof of this theorem relies on some results of [12, 14], Chapter XI, relating the representation property (1) to a condition involving a certain set of probability measures.

Remark 1 In Theorem 1 the definition of the space $L(Z)$ is crucial, as shown by a counterexample in [19]. From reference [16] we obtain that $L(Z)$ must be the largest class of integrands over which multidimensional integrals with respect to Z can be defined, as done implicitly in [11]. Hence by Theorem 4.6 of [12] we have that $L(Z)$ is the space of the vector-valued, predictable processes $H = (H_t^1, \dots, H_t^d)_{t \in [0, T]}$ such that

$$\int_0^t \sum_{i,j=1}^d H_s^i H_s^j d[Z^i, Z^j]_s, \quad t \in [0, T] \quad (3)$$

is locally integrable.

Completeness can be easily characterized in some particular cases, as shown by the following examples.

Example 1 Consider a market with a finite number of assets in discrete time $\{0, \dots, T\}$ and let $\mathcal{P}_t$ be the partition of Ω underlying $\mathcal{F}_t$. For each cell A of $\mathcal{P}_t$, $t \in \{0, \dots, T-1\}$, we define as *splitting index* of A the number $K_t(A)$ of cells of $\mathcal{P}_{t+1}$ that are contained in A . Then completeness can be characterized as follows.

Proposition 1 (Proposition 2.12 of [10]). *Let $\mathbb{P} \neq \emptyset$ and suppose that the securities are not redundant.^b Then the model is complete if and only if $K_t(A) = d+1$ for all $A \in \mathcal{P}_t$ and $t = 0, \dots, T-1$.*

Hence completeness is a matter of dimension. Corollary 4.2 of [23] shows that if the market is complete, then the splitting index $K_t(A)$ is determined by the price process S only, that is, for every

$t = 0, \dots, T$ and each $A \in \mathcal{P}_t$, we have $K_t(A) = \dim(\text{span}\{S_{t+1}(\omega) : \omega \in A\})$. Hence it is sufficient to check if the rank of the matrix with columns formed by the vectors $S_{t+1}(\omega)$, $\omega \in A$, equals the splitting index $K_t(A)$ of A . By using this geometric property of the sample paths of the price process, an algorithm is then provided in [23] to check if finite securities markets in discrete time are complete.

Example 2 In the case when security prices follow Itô processes on a multidimensional Brownian filtration, completeness of the market can be characterized in terms of the volatility matrix of the underlying asset prices, as shown in [3, 16, 18]. Consider a market with d risky assets given by Itô processes of the form

$$S_t^i = S_0^i \exp \left[\int_0^t \alpha_s^i ds - 1/2 \sum_{j=1}^n \int_0^t (\sigma_s^{ij})^2 ds + \sum_{j=1}^n \int_0^t \sigma_s^{ij} dW_s^j \right], \quad t \in [0, T] \quad (4)$$

$i = 1, \dots, d$, on the probability space $(\Omega, \mathcal{F}, P)$ endowed with the (augmented) natural filtration $(\mathcal{F}_t)_{t \in [0, T]}$ generated by the n -dimensional Brownian motion $W = (W_t^1, \dots, W_t^n)_{t \in [0, T]}$ with $\mathcal{F}_T = \mathcal{F}$. Here S^0 can be assumed constantly equal to 1 for the sake of simplicity. For $t \in [0, T]$ we denote by $\Sigma_t(\omega)$ the (random) volatility matrix, whose entries are given by

$$[\Sigma_t(\omega)]_{ij} = \sigma_t^{ij}(\omega), \quad i = 1, \dots, d, \quad j = 1, \dots, n \quad (5)$$

If for all $i = 1, \dots, d$, S_0^i is a positive constant, $(\alpha_t^i)_{t \in [0, T]}$ an adapted stochastic process with

$$\int_0^T |\alpha_s^i| ds < \infty, \quad \text{a.s.} \quad (6)$$

and $(\sigma_t^{ij})_{t \in [0, T]}$ are adapted stochastic processes with

$$\int_0^T (\sigma_s^{ij})^2 ds < \infty, \quad \text{a.s.} \quad (7)$$

for $j = 1, \dots, n$, then the following characterization of market completeness holds.

Theorem 2 (Theorem 4 of [3], Theorem 2.2 and 3.2 of [16]). *Let $\mathbb{P} \neq \emptyset$. Then the market is complete if and only if $P(\text{rank}(\Sigma_t) = d \text{ for almost all } t \in [0, T]) = 1$.*

For further references, see also Theorem 4.1 of [18]. Since there are n sources of randomness represented by the Brownian motions, it is natural to expect that n sufficiently independent asset prices are needed for completeness. Clearly, if $d < n$ the market cannot be complete.

Example 3 If price processes are discontinuous but with a finite number of jump sizes, then we obtain again a characterization of completeness in terms of the volatility matrix, as shown by the following theorem attributed to Bättig [3]. We set again $S^0 = 1$ and consider price processes driven by a multivariate point process^c μ with compensator $\nu(dt, dx) = K_t(dx)dt$ such that

$$S_t^i = S_0^i \varepsilon(R^i)_t, \quad t \in [0, T], \quad i = 1, \dots, d \quad (8)$$

with

$$R_t^i = \int_0^t \alpha_s^i ds + \int_{[0,t] \times E} \sigma^i(u, x)(\mu(du, dx) - \nu(du, dx)), \quad t \in [0, T], \quad i = 1, \dots, d, \quad (9)$$

where the $\sigma^i(t, x)$ s are bounded $d\mu \otimes dP$ a.e., $\mathcal{E}$ is the Doléans exponential (for the definition, we refer to Theorem I.4.61 of [13]), and $E \subset \mathbb{R}$. Note that here σ^i , μ , and ν may depend on ω , but for the sake of simplicity we do not indicate this dependence. In this context, asset prices may have jumps that can be thought of as the result of possible shocks that may trigger the market. If the cardinality $|E|$ of E is finite, we denote again by Σ_t the volatility matrix, whose row vectors are given by $(\sigma^i(t, x))_{x \in E}$, $i = 1, \dots, d$.

Theorem 3 (Theorem 5 of [3]). *Let $\mathbb{P} \neq \emptyset$, $|E| < \infty$ and $K_t(\{x\}) > 0$ for every $x \in E$. Then the market is complete if and only if $P(\text{rank}(\Sigma_t) = |E| \text{ for almost all } t \in [0, T]) = 1$.*

Furthermore, in the case of a finite number of jumps that may trigger the economy, the characterization of market completeness is similar to the Itô price process case, that is, one needs $|E|$ sufficiently independent processes for completeness in presence of the $|E|$

sources of randomness, given by the $|E|$ different possible shocks.

We have seen that the key to completeness is the predictable representation property. Hence, a natural question concerns the kind of martingales for which the predictable representation property is satisfied. For the continuous case, we have that the predictable representation property holds for diffusion processes that are martingales and have either Lipschitz coefficients [24] or a nondegenerate diffusion matrix and continuous coefficients [14]. The only one-dimensional martingales with stationary and independent increments that satisfy the predictable representation property are the Wiener and the Poisson martingales [25]. Hence the representation property holds for finite Lévy measures, but it fails for infinite Lévy measures. In the next section, we discuss the *second fundamental theorem* in the case of infinite dimensional financial markets.

Infinite Number of Assets

Many applications of hedging involve dynamic trading in principle in infinitely many securities, for example, in pricing of interest rate derivatives by using pure discount bonds or in the use of the term and strike structure of European put and call options to hedge exotic derivatives, when asset prices are driven by Lévy measures. Hence it is natural to develop infinite dimensional market models to address this kind of issues. The problem now is to establish if the *second fundamental theorem* still holds, and if the market is endowed with an infinite number of assets.

By defining a complete market *via* the density of a vector space, the *second fundamental theorem* is in [8] proved to hold true for (infinitely many) continuous and bounded asset price processes, if all the martingales with respect to the reference filtration $\mathcal{F}_t$ are continuous ([8], Theorem 6.7). In the case of a general filtration, Theorem 6.5 of [8] states that completeness is equivalent for P^* to be an extreme point of $\mathbb{P}$, that is, a weaker version of the *second fundamental theorem* holds.

The hypothesis of continuity cannot be dropped and in the presence of jumps (discontinuities) and infinitely many assets, a counterexample to the *second fundamental theorem* is provided in [2], where an economy with infinitely many assets is constructed,

in which the market is complete; yet, there exists an infinity of equivalent martingale measures. Since the formulation of this counterexample, many papers have studied the problem of extending the result of the *second fundamental theorem* to markets with infinitely many assets. Since many definitions of completeness are possible, the solution to the counterexample of [2] relies on the choice of the definition of completeness that is adopted. A first answer to this problem was provided in 1997 by Björk *et al.* [5, 6], where Theorem 6.11 shows that in the presence of infinitely many assets and a continuum of jump sizes, the uniqueness of the equivalent martingale measure is equivalent to the market being *approximately complete*, that is, every bounded contingent claim can be approached in $L^2(Q)$ for some $Q \in \mathbb{P}$ by a sequence of hedgeable claims.

In 1999, a number of papers appeared [3, 4, 15, 17] at the same time, where new definitions of market completeness were proposed in order to maintain the *second fundamental theorem*, even in complex economies. The equivalence between market completeness and uniqueness of the pricing measure is maintained by introducing a notion of market completeness that is independent both of the notion of no arbitrage and of a chosen equivalent martingale measure. In finite-dimensional markets, the definition of market completeness is given in terms of replicating value processes in economies without arbitrage possibilities and with respect to a given equivalent martingale measure. However, the issue of completeness is about the ability to replicate certain cash flows, and not about how these cash flows are valued or whether these values are arbitrage free. From this perspective, the appropriate measure to address the issue of completeness is the statistical probability measure P , and not an equivalent martingale measure that may also not exist. In reference [17], this new approach was also motivated by the empirical asset pricing literature. Moreover, an example in [3] shows an economy where the existence of an equivalent martingale measure precludes the possibility of market completeness. Hence in references [3, 4, 15, 17], the concept of exact (almost everywhere) replication of a contingent claim *via* an admissible portfolio is substituted by the notion of *approximation* of a contingent claim. The main outlines of this approach are the following.

Let $\mathbb{M}$ denote the space of the P -absolutely continuous signed measures on $\mathcal{F}_T$. Then $Q \in \mathbb{M}$ can

be interpreted as a market agent's personal way of assigning values to claims, that is, the set $\mathbb{M}$ represents the possible contingent claims valuation measures held by traders. An agent using the valuation measure $Q \in \mathbb{M}$ assigns to a contingent claim H the value $\int H dQ$. The fact that $\mathbb{M}$ is given by the P -absolutely continuous signed measures on $\mathcal{F}_T$ has two particular meanings: first that all traders agree on null events, and second, that there can be strictly positive random variables with negative personal value. For a given trader, represented by $Q \in \mathbb{M}$, two contingent claims H_1 and H_2 are approximately equal if

$$|\int (H_1 - H_2) dQ| < \epsilon \text{ for small } \epsilon > 0 \quad (10)$$

Denote the space of all bounded contingent claims by $\mathcal{C}$. The finite intersections of the sets of the form $B(H_1, \epsilon) = \{H_2 \in \mathcal{C} \mid |\int (H_1 - H_2) dQ| < \epsilon\}$, $H_1 \in \mathcal{C}$, and $\epsilon > 0$, give a basis for a topology τ^Q on $\mathcal{C}$. We endow $\mathcal{C}$ with the coarsest topology τ finer than all of the τ^Q , $Q \in \mathbb{M}$. This topology is now agent independent, that is, two claims are approximately equal if all the agents believe that their values are close. The topology τ is usually referred as the *weak* topology* on $\mathcal{C}$ [21].

An agent is then allowed to trade in a finite number of assets *via* self-financing, bounded, stopping time simple strategies that yield a bounded payoff at T . As in the previous section, a (bounded) claim is said to be attainable if it can be replicated by one of such strategies. In this setting, the market is said to be *quasicomplete* if any contingent claim $H \in \mathcal{C}$ can be approximated by attainable claims in the weak* topology induced by $\mathbb{M}$ on $\mathcal{C}$. Since the weak* topology as well as the trading strategies are agent measure independent, the same is true for this notion of completeness. Consider now the space $\mathbb{P}_\pm$ of the P -absolutely continuous signed martingale measures. Then the following generalized version of the *second fundamental theorem* holds.

Theorem 4 (The second fundamental theorem of asset pricing, Theorem 2 of [3], Theorem 1 of [4], Theorem 5 of [17]). *Let $\mathbb{P}_\pm \neq \emptyset$. Then there exists a unique P -absolutely continuous signed martingale measure if and only if the market is quasicomplete.*

The proof of this theorem relies on the theory of linear operators between locally convex topological vector spaces.

Since the market is endowed with an infinite number of assets, in principle, trading in infinitely many assets may be possible. To take this possibility into account, in [5, 6, 15, 17] portfolios consisting of infinitely many assets are allowed by considering measure-valued strategies. The result of Theorem 4 still holds in the case of market models where measure-valued strategies are allowed as shown in Theorem 6.11 of [5] and Theorem 2.1 of [15].

This approach resolves the paradox of the counterexample of [2], since the economy considered in [2] is incomplete under this new definition of market completeness. Moreover, if $\mathbb{P} \neq \emptyset$ and the number of assets is finite or the asset prices are given by continuous processes, then Theorem 5 of [4] shows that the market model is quasicomplete if and only if it is complete.

End Notes

^aWe say that a contingent claim is integrable if $E^*[X/S_T^0] < \infty$. By Definition 1, it follows that an attainable contingent claim is necessarily integrable. Hence we can restate the definition of market completeness as follows. The model is said to be *complete* if every integrable claim is attainable.

^bThe price process is said to contain a redundancy if $P(\alpha \cdot S_{t+1} = 0|A) = 1$ for some nontrivial vector α , some $t < T$, and some $A \in \mathcal{P}_t$.

^cLet E be a Blackwell space. An E -multivariate point process is an integer-valued random measure on $[0, T] \times E$ with $\mu([0, t] \times E) < \infty$ for every $\omega, t \in [0, T]$ (see Definition III.1.23 of [13]).

Expected Utility Maximization: Duality Methods

Expected utility maximization has a long tradition in modern mathematical finance. It dates back to the 1950s [18] when it provided a theoretical foundation to the (Markowitz's) mean–variance asset allocation method (see **Risk–Return Analysis**). The objective of a rational and risk-averse agent acting is captured by a concave function, the utility U of the agent (see **Utility Function**). It is typically assumed that U is increasing since the agent prefers more wealth to less. Given his/her U , the agent chooses the portfolio P^* that maximizes the agent's *expected utility* over a horizon $[0, T]$.

Some famous case studies are considered in [12, 13], where the agent is planning for retirement in a Black–Scholes (and thus complete) financial market (see **Merton Problem**). The complete market framework (see **Complete Markets**) is a convenient mathematical idealization as any conceivable risk can be hedged by cleverly investing in the market. As a consequence, independently of the specific utility of the agent, the price of any claim is also uniquely assigned since by the no-arbitrage principle it must coincide with the initial value of the hedging portfolio.

In the more realistic situation of incomplete market, when there are, for example, intrinsic, nontraded sources of risk, both the valuation and the hedging problems become highly nontrivial issues. Expected utility maximization has also turned out to perform very well in the pricing problem in the general, incomplete market setup. The related pricing techniques are known as *pricing by marginal utility* and *indifference pricing* and are discussed briefly in this article (for more details see **Utility Indifference Valuation**).

The use of increasingly more complex probabilistic models of financial assets has continued to pose new mathematical challenges. If the setup is that of general non-Markovian diffusion or semimartingale models, direct methods from stochastic optimal control (as originally done by Merton and many others after him) become increasingly difficult to handle. As first suggested by Bismut [4], *convex duality* (see

Convex Duality) is a powerful alternative approach. In the mid-1980s, with the works of Pliska [14], He and Pearson [8], Karatzas *et al.* [10], and Cox and Huang [5] this new methodology started to fully develop. Relying on convex duality (see **Convex Duality**) and martingale (see **Martingales**) methods, it enables the treatment of the most general cases. The price to pay for the achieved generality is that the results obtained have a mathematical existence–uniqueness–characterization form. As is always the case, explicit calculations require the specification of a (very) tractable model.

The presentation given here is based on the convex duality approach, in a general semimartingale model. For a treatment of the same problem with martingale methods in a diffusion context, see **Expected Utility Maximization** or [9].

Examples

Consider an agent who is a price taker, that is, his/her actions do not affect market prices, and whose goal is to trade dynamically in a financial market up to a horizon T , in order to achieve maximum expected utility. A host of features can be taken into account, such as the initial endowment, the possibility of intertemporal consumption, and the presence of a random endowment at time T . A list of various situations is given in the following. The mathematical details are discussed in the next section.

1. Maximizing Utility of Terminal Wealth

The preferences of the investor are represented by a von Neumann–Morgenstern utility function

$$U : \mathbb{R} \rightarrow [-\infty, +\infty) \quad (1)$$

which must be not identical to $-\infty$, increasing, and concave.

Typical examples are $U(x) = \ln x$, $U(x) = \frac{1}{\alpha} x^\alpha$ with $\alpha < 1$, $\alpha \neq 0$, where it is intended that $U(x) = -\infty$ outside the domain, and $U(x) = -\frac{1}{\gamma} e^{-\gamma x}$ with $\gamma > 0$.

No consumption occurs before time T . The agent has the initial endowment x and can invest in the financial market. The resulting optimization problem is

$$\sup_{k \in K(x)} E[U(k)] \quad (2)$$

where $K(x)$ is the set of random wealths that can be obtained at time T (terminal wealths) with initial wealth x .

The formulation of the problem with random endowment, namely, when the agent receives at T an additional cashflow B (say, an option), is the following:

$$\sup_{k \in K(x)} E[U(k + B)] \quad (3)$$

as his/her terminal possible wealths now are of the form $k + B$.

2. Maximizing Utility of Consumption

Suppose that the agent is not particularly interested in consumption at the terminal time T , but rather he/she is willing to consume over the entire planning horizon. A consumption plan C for the agent is determined by its random rate of consumption $c(t)$ at time t for all $t \in [0, T]$. It is evident from the financial perspective that the rate $c(t)$ must be nonnegative, so the consumption in the interval $[t, t + dt]$ increases by the quantity $c(t)dt$. The goal of the agent is thus the selection of the best consumption plan over $[0, T]$, starting with an initial endowment $x \geq 0$. The utility function will now measure the degree of satisfaction with the intertemporal consumption or better with the rate of consumption. As this measure may change over the time, the utility also depends on the time parameter:

$$\bar{U} : [0, T] \times \mathbb{R} \rightarrow [-\infty, +\infty) \quad (4)$$

When t is fixed, then $\bar{U}(t, \cdot)$ is a utility function with the same properties as in case (1). As the rate of consumption cannot be negative, $\bar{U}(t, x) = -\infty$ when $x < 0$. The agent may clearly benefit from the opportunity of investing in the financial market, so in general his/her position can be expressed by a consumption plan C and a dynamically changing portfolio P . If $X^{C,P}(t)$ is the total wealth of the position (C, P) at time t , then as there is no inflow of cash the variation of the wealth in $[t, t + dt]$ must satisfy

$$dX^{C,P}(t) = -c(t)dt + dV^P(t) \quad (5)$$

where $dV^P(t)$ is the variation of the value of the portfolio P at time t due to market fluctuations. Let $\mathcal{A}(x)$ indicate the set of all such consumption plans—portfolios (C, P) when starting from

the wealth level x . The maximization is then that of the expected integrated utility from the rate of consumption:

$$\sup_{(C,P) \in \mathcal{A}(x)} E \left[\int_0^T \bar{U}(t, c(t)) dt \right] \quad (6)$$

3. Maximizing Utility of Terminal Wealth and Consumption

Alternatively, the agent may wish to maximize expected utility from terminal wealth and intertemporal consumption given his/her initial wealth $x \geq 0$. Therefore, there are two utilities, U and $\bar{U}$, from terminal wealth and from the rate of consumption, respectively. Let $\mathcal{A}(x)$ be the set of the possible consumption plans—portfolios (C, P) , obtained with initial wealth x , and let $X^{C,P}(T)$ be the terminal wealth from the choice (C, P) . Then the optimal consumption–investment is the couple (C^*, P^*) that solves

$$\sup_{(C,P) \in \mathcal{A}(x)} \left\{ E \left[\int_0^T \bar{U}(t, c(t)) dt \right] + E [U(X^{C,P}(T))] \right\} \quad (7)$$

The case selected in the following section for the illustration of the duality technique and the main results is the first, that is, utility maximization of terminal wealth. When intertemporal consumption is taken into account, similar results can be proved. In addition, case 3 turns out to be a superposition of cases 1 and 2, as shown in Chapters 3, 6 of [9].

Maximizing the Utility of (Discounted) Terminal Wealth

An analysis of any optimization problem relies on a precise definition of the domain of optimization and the objective function. Therefore, the study of maximization (2) requires a specification of

1. the financial market model and the admissible terminal wealths;
2. the technical assumptions on U ; and
3. some joint condition on the market model and the utility function.

1. The financial market model considered is frictionless and consists of N risky assets and one

risk-free asset (money market account). Although it is not necessary, for the sake of convenience, it is assumed that the risk-free asset, S^0 , is constantly equal to 1, that is, the prices are *discounted*. The N risky assets are globally indicated by $S = (S^1, \dots, S^N)$. The trading can occur continuously in $[0, T]$. $S = (S_t)_{t \leq T}$ is, in fact, an $\mathbb{R}^N$ -valued, continuous-time process, defined on a filtered probability space $(\Omega, (\mathcal{F}_t)_{t \leq T}, \mathbb{P})$. Since the wealth from an investment in this market is a (stochastic) integral, S is assumed to be a semimartingale so that the object “integral with respect to S ” is mathematically well defined (see **Stochastic Integrals**). For expository reasons, S is a *locally bounded* semimartingale. This class of models is already very general, as all the diffusions are locally bounded semimartingales, as well as any jump-diffusion process with bounded jumps.

The agent has an initial endowment x and there are no restrictions on the quantities he/she can buy, sell, or sell short. $H_t = (H_t^1, \dots, H_t^N)$ is the random vector with the number of shares of each risky asset that the agent holds in the infinitesimal interval $[t, t + dt]$. B_t represents the number of shares of the risk-free asset held in the same interval. $H = (H_t)_t$ and $B = (B_t)_t$ are the corresponding processes and are referred to as the *strategy* of the agent. To be technically precise, H must be a predictable process and B a semimartingale. As there is no consumption and no infusion of money in the trading period $[0, T]$, the wealth from a strategy (H, B) is the process X that solves

$$\begin{cases} dX_t = (H_t dS_t + B_t dS_t^0) = H_t dS_t \\ X_0 = x \end{cases} \quad (8)$$

or, in integral form, $X_t = x + \int_0^t H_s dS_s$. This can be equivalently stated as the strategy (H, B) is self-financing. Since $dS^0 = 0$, the self-financing condition enables a representation of the wealth X only in terms of H . This is the reason one typically refers to H only as *the strategy*.

As usual in continuous-time trading (see **Fundamental Theorem of Asset Pricing**) to avoid phenomena like doubling strategies, not every self-financing H is allowed. A self-financing strategy H is said to be *admissible* only if during the trading the losses do not exceed a finite credit line. That is, H is admissible

if there exists some constant $c > 0$ such

$$\text{for all } t \in [0, T], \quad \int_0^t H_s dS_s \geq -c \quad \mathbb{P} - a.s. \quad (9)$$

so that for any x the wealth process $X = x + \int H_s dS_s$ is also bounded from below. Maximizing expected utility from terminal wealth means, in fact, *maximizing expected utility from the set $K(x)$ of those random variables X_T that can be represented as $X_T = x + \int_0^T H_t dS_t$ with H admissible in the sense of equation (9).*

Hereafter, the notation $E[\cdot]$ indicates $\mathbb{P}$ -expectation. When considering expectation under another probability $\mathbb{Q}$, the notation is explicitly $E_{\mathbb{Q}}[\cdot]$.

As shown by Delbaen and Schachermayer [7] a financially relevant set of probabilities is $\mathcal{M}^e$, namely, the set of the equivalent (local) martingale probabilities for S . When the market is complete, this set consists of only one probability, but in the general, incomplete market case, this set is infinite. Under each probability, $\mathbb{Q} \in \mathcal{M}^e$ S is a (local) martingale and thus $\mathbb{Q}$ is a risk-neutral probability. This is the theoretical justification for the use of each of these $\mathbb{Q}$ s as a pricing measure for any derivative claim B , with (arbitrage-free) price given by the expectation $E_{\mathbb{Q}}[B]$.

However, we need the less restrictive set $\mathcal{M}$ of the absolutely continuous (local) martingale probabilities $\mathbb{Q}$ for S , as this is the set that will show up in the dual problem. The set $\mathcal{M}$ can be characterized in the following manner:

$$\mathcal{M} = \left\{ \mathbb{Q} \ll \mathbb{P} \mid E_{\mathbb{Q}} \left[\int_0^T H_t dS_t \right] \leq 0 \quad \forall \text{ adm. } H \right\} \quad (10)$$

as the set of absolutely continuous probability measures that give nonpositive expectation to the terminal wealths from admissible self-financing strategies starting with zero wealth. Therefore, given any $X_T \in K(x)$ and any $\mathbb{Q} \in \mathcal{M}$,

$$E_{\mathbb{Q}}[X_T] = E_{\mathbb{Q}} \left[x + \int_0^T H_t dS_t \right] \leq x \quad (11)$$

2. Hypothesis on U . As a case study, let us assume that U is finite valued on $\mathbb{R}$, that is, the wealth can become arbitrarily negative (the closest

references are [2, 16]). A typical example is the exponential utility. The reason we prefer the exponential utility (and all the other utilities with the properties listed below) to, for example, the logarithmic or the power utilities is that the dual problem is easier to interpret. References for the case when there are constraints on the wealth (then U is finite only on a half-line), like $U(x) = \ln x$ or $U(x) = \frac{1}{\alpha}x^\alpha$, are [11], [17], and the bibliography contained therein.

A main difficulty the reader may encounter when comparing this literature is that the language and style in the papers differ. Very recently, Biagini and Frittelli [3] proposed a unifying approach that works both for the case of U finite on all $\mathbb{R}$ and for the case of U finite only on a half-line. The result there is enabled by the choice of an innovative duality (an Orlicz space duality), naturally induced by the utility function U .

Regarding U , it is here required that

- U is strictly concave, strictly increasing, and differentiable over $(-\infty, +\infty)$ and
- $\lim_{x \downarrow -\infty} U'(x) = -\infty$ and $\lim_{x \rightarrow +\infty} U'(x) = 0$ (these are known as the *Inada condition* on the marginal utility U').

In addition, U must satisfy the reasonable asymptotic elasticity condition $RAE(U)$ introduced in [11, 16]:

$$\liminf_{x \rightarrow -\infty} \frac{xU'(x)}{U(x)} > 1, \quad \limsup_{x \rightarrow +\infty} \frac{xU'(x)}{U(x)} < 1 \quad (12)$$

In the cited references, it is also shown that this condition is necessary and sufficient for the duality to work properly if U is fixed and one considers all possible financial markets. However, *within a specific market model*, one may state more general necessary and sufficient conditions on U that enable the duality approach and ensure the existence of the optimal investment. We choose to impose $RAE(U)$ for it has the advantage that it can be easily verified. Note also that $RAE(U)$ is already satisfied by the commonly used utility functions, for example, by the classic exponential function $U(x) = -\frac{1}{\gamma}e^{-\gamma x}$.

3. The convex conjugate V and a joint condition between preferences and the market. The conjugate V of U is the function

$$V(y) = \sup_x \{U(x) - yx\} \quad (13)$$

and, apart from some minus signs, it coincides with the Fenchel conjugate of U (see **Convex Duality**). Thus, V is a convex function, which is identically equal to $+\infty$ when $y < 0$. It is also differentiable on $(0, +\infty)$ and its derivative is $V' = -(U')^{-1}$. Traditionally, the inverse of the marginal utility $(U')^{-1}$ is denoted by I . By mere definition of V , for all x, y , the Fenchel inequality holds

$$U(x) \leq xy + V(y) \quad (14)$$

and the above relation is, in fact, an equality iff $y = U'(x)$ or equivalently $x = (U')^{-1}(y) = I(y)$. Also note that

$$U(x) = \inf_y \{xy + V(y)\} = \inf_{y>0} \{xy + V(y)\} \quad (15)$$

The typical example (and most used) is the following couple (U, V) :

$$U(x) = -\frac{1}{\gamma}e^{-\gamma x}$$

$$V(y) = \begin{cases} \frac{1}{\gamma}(y \ln y - y) & y > 0 \\ 0 & y = 0 \\ +\infty & y < 0 \end{cases} \quad (16)$$

Let us recall that a probability $\mathbb{Q}$ absolutely continuous with respect to $\mathbb{P}$ is said to have *finite generalized entropy* (or, also, *finite V -divergence*), if its density $\frac{d\mathbb{Q}}{d\mathbb{P}}$ is integrable when composed with V

$$E \left[V \left(\frac{d\mathbb{Q}}{d\mathbb{P}} \right) \right] < +\infty \quad (17)$$

The joint condition required between preferences and the market is actually a condition between V and the set of probabilities $\mathcal{M}$, which is as follows:

Condition 1 There exists a $Q^0 \in \mathcal{M}$ with finite generalized entropy, that is, $E \left[V \left(\frac{dQ^0}{dP} \right) \right] < +\infty$.

Duality in Complete Market Models

Suppose that the market is complete and arbitrage free. Thus, there exists a unique equivalent martingale measure $\mathbb{Q} \in \mathcal{M}^e$, which, by Condition 1, has also

finite generalized entropy. Let us restate problem (2), the *primal* problem

$$u(x) := \sup_{X_T \in K(x)} E[U(X_T)] \quad (18)$$

where $u(x)$ denotes the optimal level of the expected utility. It is not difficult to derive an upper bound for $u(x)$. From inequality (14), in fact, for all $X_T \in K(x)$ and for all $y > 0$

$$U(X_T) \leq X_T y \frac{d\mathbb{Q}}{d\mathbb{P}} + V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right) \quad (19)$$

and taking $\mathbb{P}$ -expectations on both sides

$$E[U(X_T)] \leq xy + E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] \quad (20)$$

because $E\left[X_T \frac{d\mathbb{Q}}{d\mathbb{P}}\right] = E_{\mathbb{Q}}[X_T] \leq x$. Therefore, taking the supremum over X_T and the infimum over y ,

$$\begin{aligned} u(x) &= \sup_{X_T \in K(x)} E[U(X_T)] \leq \inf_{y>0} xy + E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] \\ &\quad (21) \end{aligned}$$

As noted by Merton, the above supremum is not necessarily reached over the restricted set of admissible terminal wealths $K(x)$. Following a well-known procedure in the calculus of variations, a *relaxation* of the primal problem allows to obtain the optimal terminal wealth. Here, this means enlarging $K(x)$ slightly and considering the larger set

$$K_{\mathbb{Q}}(x) := \{k \in L^1(\mathbb{Q}) \mid E_{\mathbb{Q}}[k] \leq x\} \quad (22)$$

$K_{\mathbb{Q}}(x)$ is simply the set of claims that have initial price smaller or equal to the initial endowment x . An application of the separating hyperplane theorem gives that $K_{\mathbb{Q}}(x)$ is the norm closure of $K(x) - L_+^1(\mathbb{Q})$ in $L^1(\mathbb{Q})$. Then, an approximation argument shows that the optimal expected value $u(x)$ and

$$u_{\mathbb{Q}}(x) := \sup_{k \in K_{\mathbb{Q}}(x)} E[U(k)] \quad (23)$$

are, in fact, equal. The *relaxed* maximization problem over $K_{\mathbb{Q}}(x)$ is much simpler than the original one over $K(x)$. The replication-with-admissible-strategies issue has been removed and there is just an inequality constraint, given by the pricing measure $\mathbb{Q}$. To find

out the value $u_{\mathbb{Q}}(x) = u(x)$, one can now apply the traditional Lagrange multiplier method to get

$$\begin{aligned} u_{\mathbb{Q}}(x) &= \sup_{k \in K_{\mathbb{Q}}(x)} E[U(k)] \\ &= \sup_{k \in L^1(\mathbb{Q})} \inf_{y>0} \{E[U(k)] + y(x - E_{\mathbb{Q}}[k])\} \end{aligned} \quad (24)$$

The dual problem is defined by exchanging the inf and the sup in the above expression:

$$\inf_{y>0} \sup_{k \in L^1(\mathbb{Q})} \{E[U(k)] + y(x - E_{\mathbb{Q}}[k])\} \quad (25)$$

From [15 Theorem 21] or from a direct computation, the inner sup is actually equal to

$$xy + E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] \quad (26)$$

so that the dual problem takes the traditional form

$$\inf_{y>0} \left\{ xy + E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] \right\} \quad (27)$$

which is exactly the right-hand side of equation (21).

Thanks to Condition 1, the dual problem is always finite valued and so is u . *A priori*, however, one has only the chain $u(x) = u_{\mathbb{Q}}(x) \leq \inf_{y>0} \left\{ xy + E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] \right\}$, but under the current assumptions there is *no duality gap*:

$$u(x) = u_{\mathbb{Q}}(x) = \inf_{y>0} \left\{ xy + E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] \right\} \quad (28)$$

the infimum is a minimum and the supremum over $K_{\mathbb{Q}}(x)$ is reached. In fact, the *RAE(U)* condition on the utility function U implies that $E\left[V\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] < +\infty \forall y > 0$, so the infimum in (27) can be obtained by differentiation under the expectation sign. The dual minimizer y^* (which depends on x) is then the unique solution of

$$x + E_{\mathbb{Q}}\left[V'\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] = 0 \quad (29)$$

or, equivalently, y^* is the unique solution of

$$E_{\mathbb{Q}}\left[I\left(y \frac{d\mathbb{Q}}{d\mathbb{P}}\right)\right] = x \quad (30)$$

Therefore, the (unique) optimal claim is $k^* = I\left(y^* \frac{dQ}{dP}\right)$ because it verifies the following:

- the balance equation $E_Q[k^*] = x$, so $k^* \in K_Q(x)$ and
- the Fenchel equality

$$U(k^*) = k^* y^* \frac{dQ}{dP} + V\left(y^* \frac{dQ}{dP}\right) \quad (31)$$

from which, by taking the $\mathbb{P}$ -expectations, we get

$$\begin{aligned} E[U(k^*)] &= y^* E\left[k^* \frac{dQ}{dP}\right] + E\left[V\left(y^* \frac{dQ}{dP}\right)\right] \\ &= y^* x + E\left[V\left(y^* \frac{dQ}{dP}\right)\right] \end{aligned} \quad (32)$$

which proves the main equality (28).

By market completeness, the martingale representation theorem applies, so that k^* can be obtained via a self-financing strategy H^* :

$$k^* = x + \int_0^T H_t^* dS_t \quad (33)$$

though H^* is not admissible in general, that is, when optimally investing, the agent can incur arbitrarily large losses.

Moreover, as a function of x , the optimal value $u(x)$ is also a utility function finite on $\mathbb{R}$, with the same properties of U . The duality equation (28) shows that u and

$$v(y) = \begin{cases} E\left[V\left(y \frac{dQ}{dP}\right)\right] & \text{if } y \geq 0 \\ +\infty & \text{otherwise} \end{cases} \quad (34)$$

are conjugate functions.

The relationship between the primal and dual optima can also be expressed as

$$\frac{dQ}{dP} = \frac{1}{y^*} U'(k^*) \quad (35)$$

which amounts to saying that $\frac{dQ}{dP}$ is proportional to one's marginal utility from the optimal investment. Therefore, in the complete market case, pricing by taking Q -expectations coincides with the *pricing by marginal utility principle*, introduced in the option pricing context by Davis [6].

Duality in Incomplete Market Models

The same methodology applies to the incomplete market framework, but the technicalities require some more effort. The main results are (more or less intuitive) generalizations of what happens in the complete case, as summarized below (see [2, 16] for the proofs).

1. The duality relation is the natural generalization of equation (28):

$$\begin{aligned} u(x) &= \sup_{X_T \in K(x)} E[U(X_T)] \\ &= \inf_{y > 0, Q \in \mathcal{M}} \left\{ xy + E\left[V\left(y \frac{dQ}{dP}\right)\right] \right\} \end{aligned} \quad (36)$$

and there exists a unique couple of dual minimizers y^*, Q^* .

2. As in the complete case, the supremum of the expected utility on $K(x)$ may be not reached. $K_V(x)$ denotes the set of $k \in L^1(Q)$ such that $E_Q[k] \leq x$ for all $Q \in \mathcal{M}$ with finite generalized entropy. Then, the supremum of the expected utility on $K_V(x)$ coincides with the value $u(x)$ and it is a maximum. The claim $k^* \in K_V$ attaining the maximum is unique and the relationship between primal and dual optima still holds

$$\frac{dQ^*}{dP} = \frac{1}{y^*} U'(k^*) \quad (37)$$

3. Q^* may be not equivalent to $\mathbb{P}$. However, in the case $Q^* \sim \mathbb{P}$, k^* can be obtained through a self-financing strategy H^* , albeit not admissible in general.
4. The optimal value u as a function of the initial endowment x is a utility function, with the same properties of U . In fact, it is finite on $\mathbb{R}$, strictly concave, strictly increasing, it verifies the Inada conditions, and $RAE(u)$ holds. The duality relation (36), rewritten as $u(x) = \inf_{y > 0} \{xy + v(y)\}$ with

$$v(y) = \begin{cases} \inf_{Q \in \mathcal{M}} E\left[V\left(y \frac{dQ}{dP}\right)\right] & \text{if } y \geq 0 \\ +\infty & \text{otherwise} \end{cases} \quad (38)$$

shows that u and v are conjugate functions (see **Convex Duality**).

As $\mathbb{Q}^*$ results from a minimax theorem, it is also known as the *minimax measure*. For the applications, it is important to know that there are easy sufficient conditions that guarantee that $\mathbb{Q}^*$ is equivalent to $\mathbb{P}$, such as the following: (i) $U(+\infty) = +\infty$ as noted in [1] or (ii) in case $U(x) = -\frac{1}{\gamma}e^{-\gamma x}$, the existence of a $\mathbb{Q} \in \mathcal{M}^e$ with finite generalized entropy (see [17] for an extensive bibliography).

When $\mathbb{Q}^*$ is indeed equivalent to $\mathbb{P}$, its selection in the class of all risk-neutral, equivalent probabilities $\mathcal{M}^e$ as the pricing measure is economically motivated by its proportionality to the marginal utility from the optimal investment.

Utility Maximization with Random Endowment

Under all the conditions stated above (on the market, on U , and on both), suppose that the agent has a random endowment B at T , in addition to the initial wealth x . For example, B can be the payoff of a European option expiring at T . The agent's goal is still maximizing of expected utility from terminal wealth, which now becomes

$$u(x, B) := \sup_{X_T \in K(x)} E[U(B + X_T)] \quad (39)$$

The duality results, in this case, are similar to the ones just shown. In fact,

$$\begin{aligned} u(x, B) \\ = \min_{y > 0, \mathbb{Q} \in \mathcal{M}} \left\{ xy + yE_{\mathbb{Q}}[B] + E \left[v \left(y \frac{d\mathbb{Q}}{d\mathbb{P}} \right) \right] \right\} \end{aligned} \quad (40)$$

Note that the maximization without the claim can be seen as a particular case of the one above, with $B = 0$: $u(x, 0) = u(x)$. The solution of a utility maximization problem with random endowment is the key step to the indifference pricing technique. The (buyer's) indifference price of B is, in fact, the unique price p_B that solves

$$u(x - p, B) = u(x, 0) \quad (41)$$

This means that the agent is indifferent, that is, he/she has the same (optimal expected) utility, between (i) paying p_B at time $t = 0$ and receiving B at T and (ii) not entering into a deal for the claim B .

Change of Numeraire

Consider a financial market model with nondividend paying asset price processes $(S^0, S^1, \dots, S^N)$ living on a filtered probability space $(\Omega, \mathcal{F}, \mathbf{F}, P)$, where $\mathbf{F} = \{\mathcal{F}_t\}_{t \geq 0}$ and P is the objective probability measure. For general results concerning completeness, self-financing portfolios, martingale measures, and arbitrage, (see **Arbitrage Strategy; Fundamental Theorem of Asset Pricing; Risk-neutral Pricing**).

We choose the asset S^0 as the *numeraire asset*, and we assume that $S_t^0 > 0$ with probability 1. From general theory, we know that (modulo integrability and technical conditions) the market is free of arbitrage if and only if there exists a measure $Q^0 \sim P$ such that the normalized price processes

$$\frac{S_t^0}{S_t^0}, \frac{S_t^1}{S_t^0}, \dots, \frac{S_t^N}{S_t^0}$$

are Q^0 martingales. Using the notation $Z^i = S^i/S^0$, thus we also have, apart from the nominal price system $S^0, S^1, \dots, S^N$, the normalized price system $Z^0, Z^1, \dots, Z^N$. The economic importance of the normalized system is clarified by the following standard result.

Proposition 1 *With notation as defined above the following hold.*

- A portfolio is self-financing in the S system if and only if it is self-financing in the Z system.
- A portfolio is an arbitrage opportunity in the S system if and only if it is an arbitrage in the Z system.
- The S market is complete if and only if the Z market is complete.
- In the Z market, the asset Z^0 has the property that $Z_t^0 \equiv 1$, so it represents a bank account with zero interest rate.

If $X \in \mathcal{F}_T$ is a fixed contingent claim with exercise date T , and if we denote the (not necessarily unique) arbitrage-free price process of X by $\Pi_t[X]$, then by applying the above-mentioned result to the extended market $S^0, S^1, \dots, S^N, \Pi_t[X]$ we see that $\Pi_t[X]/S_t^0$ is a Q^0 martingale, and using this fact together with the obvious fact that $\Pi_T[X] = X$ we obtain the basic

pricing formula:

$$\Pi_t[X] = S_t^0 E^0 \left[\frac{X}{S_T^0} \middle| \mathcal{F}_t \right] \quad (1)$$

where E^0 denotes integration with respect to (w.r.t.) Q^0 .

Very often one uses the bank account B with dynamics

$$dB_t = r_t B_t dt, \quad B_0 = 1 \quad (2)$$

where r is the short rate, as numeraire. The corresponding martingale measure Q^B is then often denoted by Q and referred to as “the risk neutral martingale measure”. In this case, the pricing formula becomes

$$\Pi_t[X] = E^Q \left[e^{-\int_t^T r_s ds} X \middle| \mathcal{F}_t \right] \quad (3)$$

In many concrete situations, the computational work needed for the determination of arbitrage-free prices can be drastically reduced by a clever choice of numeraire, and the purpose of this article is to analyze such changes.

To set the scene, we consider a fixed risk neutral martingale measure Q for the numeraire B , and an alternative numeraire asset S^0 with the corresponding martingale measure Q^0 . Our first task is to find the measure transformation between Q and Q^0 .

To see what Q^0 must look like, we consider a fixed time T and an arbitrarily chosen T -claim X . Assuming enough integrability we then know that, by using B as the numeraire, the arbitrage-free price of X at time $t = 0$ is given as

$$\Pi_0[X] = E^Q \left[\frac{X}{B_T} \right] \quad (4)$$

On the other hand, using S^0 as numeraire, the price is also given by the following formula:

$$\Pi_0[X] = S_0^0 E^0 \left[\frac{X}{S_T^0} \right] \quad (5)$$

Defining the likelihood process L by $L_t = dQ^0/dQ$ on $\mathcal{F}_t$, we thus have

$$E^Q \left[\frac{X}{B_T} \right] = S_0^0 E^0 \left[L_T \frac{X}{S_T^0} \right] \quad (6)$$

Since this holds for all $X \in \mathcal{F}_T$, we have the following basic result.

Proposition 2 *Under the above-mentioned assumptions, the likelihood process L , defined as*

$$L_t = \frac{dQ^0}{dQ}, \quad \text{on } \mathcal{F}_t, \quad 0 \leq t \leq T \quad (7)$$

is given by the formula

$$L_t = \frac{S_t^0}{S_0^0 \cdot B_t} \quad (8)$$

We note that since S^0/B is a Q martingale, the likelihood process L is also, as expected, a Q martingale.

As an immediate corollary we have the following.

Proposition 3 *Assume that the S^0 dynamics under the Q measure are of the form*

$$dS_t^0 = r_t S_t^0 dt + S_t^0 \sigma_t dW_t^Q \quad (9)$$

where W^Q is a d -dimensional Q Wiener process, r is the short rate, and σ is a d -dimensional optional row vector process. Then the dynamics for the likelihood process L are of the form

$$dL_t = L_t \sigma_t dW_t^Q \quad (10)$$

We can thus easily construct the relevant Girsanov transformation directly from the volatility of the S^0 -process.

We can, in a straightforward manner, extend Proposition 3 to change from one numeraire Q^0 to another numeraire Q^1 . The proof is obvious.

Proposition 4 *Let S^0 and S^1 be two strictly positive numeraire assets with the corresponding martingale measures Q^0 and Q^1 . Denote the likelihood process $L^{0,1}$ as*

$$L_t^{0,1} = \frac{dQ^1}{dQ^0}, \quad \text{on } \mathcal{F}_t \quad (11)$$

Then $L^{0,1}$ is given by

$$L_t^{0,1} = \frac{S_t^1}{S_t^0} \cdot \frac{S_0^0}{S_0^1} \quad (12)$$

Remark 1 It may perhaps seem surprising that even in the case of an incomplete market, we obtain a

unique martingale measure Q^0 . In more detail, the situation is as follows.

- If the market is incomplete, then there will exist several risk neutral measures Q .
- Each of these measures generates a different price system, defined by the pricing formula (3).
- Choosing one particular Q is thus equivalent to choosing one particular price system.
- For a given numeraire S^0 , there will also exist several different martingale measures Q^0 .
- Each of these measures generates a different price system, defined by the pricing formula (1).
- If a risk neutral measure Q and thus a price system are fixed, there exists a unique measure Q^0 such that Q^0 generates the same price system as Q .
- The measure transformations considered here are precisely those corresponding to a change of measure within a given price system.

Pricing Homogeneous Contracts

Using a numeraire S^0 is particularly useful when the claim X is of the form $X = S_T^0 \cdot Y$, since then we obtain the following simple expression:

$$\Pi_t[X] = S_t^0 E^0[Y|\mathcal{F}_t] \quad (13)$$

A typical example when this situation occurs is when dealing with derivatives defined in terms of several underlying assets. Assume, for example, that we are given two asset prices S^0 and S^1 , and that the contract X to be priced is of the form $X = \Phi(S_T^0, S_T^1)$, where Φ is a given linearly homogeneous function. Using the standard machinery, we would have to compute the price as

$$\Pi_t[X] = E^0 \left[e^{-\int_t^T r(s) ds} \Phi(S_T^0, S_T^1) \middle| \mathcal{F}_t \right] \quad (14)$$

which essentially amounts to the calculation of a triple integral. If we instead use S^0 as numeraire we have

$$\begin{aligned} \Pi_t[X] &= S_t^0 E^0 \left[\frac{1}{S_T^0} \Phi(S_T^0, S_T^1) \middle| \mathcal{F}_t \right] \\ &= S_t^0 E^0 \left[\Phi \left(1, \frac{S_T^1}{S_T^0} \right) \middle| \mathcal{F}_t \right] \end{aligned}$$

$$= S_t^0 E^0[\varphi(Z_T) \mathcal{F}_t] \quad (15)$$

where $\varphi(z) = \Phi(1, z)$ and $Z_T = S_T^1 / S_T^0$. Note that the factor S_t^0 is the price of the traded asset S^0 at time t , so this quantity does not have to be computed—it can be directly observed on the market. Thus, the computational work is reduced to computing a single integral.

As an example, assume that we have two stocks, S^0 and S^1 , with price processes of the following form under the objective probability P :

$$dS_t^0 = \alpha S_t^0 dt + \sigma S_t^0 d\tilde{W}_t^0 \quad (16)$$

$$dS_t^1 = \beta S_t^1 dt + \delta S_t^1 d\tilde{W}_t^1. \quad (17)$$

Here $\tilde{W}^0$ and $\tilde{W}^1$ are assumed to be independent P -Wiener processes, but it would also be easy to treat the case when there is a coupling between the two assets.

Under Q the price dynamics will be given as

$$dS_t^0 = r S_t^0 dt + \sigma S_t^0 dW_t^0 \quad (18)$$

$$dS_t^1 = r S_t^1 dt + \delta S_t^1 dW_t^1 \quad (19)$$

where W^0 and W^1 are Q -Wiener processes, and from Proposition 3 it follows that the Girsanov transformation from Q to Q^0 has a likelihood process with dynamics given as

$$dL_t = L_t \sigma dW_t^0 \quad (20)$$

The T -claim to be priced is an exchange option, which gives the holder the right, but not the obligation, to exchange one S^0 share for one S^1 share at time T . Formally, this means that the claim is given by $X = \max[S_T^1 - S_T^0, 0]$, and we note that we have a linearly homogeneous contract function. From equation (15), the price process is given as

$$\Pi_t[X] = S_t^0 E^0[\max[Z_T - 1, 0] | \mathcal{F}_t] \quad (21)$$

with $Z(t) = S_t^1 / S_t^0$. We are thus, in fact, valuing a European call option on Z_T , with strike price $K = 1$.

By construction, Z will be a Q^0 -martingale, and since a Girsanov transformation will not affect the volatility, it follows easily from equations (16) and (17) that the Q^0 -dynamics of Z are given by

$$dZ_t = Z_t \sqrt{\sigma^2 + \delta^2} dW_t \quad (22)$$

where W is a standard Q^0 -Wiener process. The price is thus given by the following formula:

$$\Pi_t[X] = S_t^0 \cdot c(t, Z_t) \quad (23)$$

Here $c(t, z)$ is given directly by the Black–Scholes formula as the price of a European call option, valued at t , with time of maturity T , strike price $K = 1$, short rate $r = 0$, on a stock with volatility $\sqrt{\sigma^2 + \delta^2}$ and price z .

Forward Measures

We now specialize the theory to the case when the chosen numeraire is a zero coupon bond. As can be expected, this choice of numeraire is particularly useful when dealing with interest rate derivatives.

Suppose, therefore, that we are given a specified bond market model with a fixed risk neutral martingale measure Q (always with B as numeraire). For a fixed time of maturity T , we now choose the price process $p(t, T)$, of a zero coupon bond maturing at T , as our new numeraire.

Definition 1 *The T -forward measure Q^T is defined as*

$$L_t^T = \frac{dQ^T}{dQ} \quad (24)$$

on $\mathcal{F}_t$ for $0 \leq t \leq T$ where L^T is defined as

$$L_t^T = \frac{p(t, T)}{B_t p(0, T)} \quad (25)$$

Observing that $p(T, T) = 1$ we have the following useful pricing formula as an immediate corollary of Proposition 3.

Proposition 5 *For any sufficiently integrable T -claim X , we have the pricing formula*

$$\Pi_t[X] = p(t, T) E^T[X | \mathcal{F}_t] \quad (26)$$

where E^T denotes integration w.r.t. Q^T .

Note again that the price $p(t, T)$ does not have to be computed. It can be observed directly on the market at time t .

A natural question to ask is when Q and Q^T coincide. This occurs if and only if we Q -a.s. have

$L^T(T) = 1$, that is when

$$1 = \frac{p(T, T)}{B_T p(0, T)} = \frac{e^{-\int_0^T r(s) ds}}{E^Q \left[e^{-\int_0^T r(s) ds} \right]} \quad (27)$$

that is if and only if r is deterministic.

The General Option Pricing Formula

We now present a fairly general formula for the pricing of European call options. Therefore, assume that we are given a financial market with a (possibly stochastic) short rate r and a strictly positive asset price process S . We also assume the existence of a risk neutral martingale measure Q .

Consider now a fixed time T , and a European call on S with exercise date T and strike price K . We are, thus, considering the T -claim:

$$X = \max[S_T - K, 0] \quad (28)$$

The main trick when dealing with options is to write X as

$$\begin{aligned} X &= (S_T - K) \cdot I\{S_T \geq K\} \\ &= S_T \cdot I\{S_T \geq K\} - K \cdot I\{S_T \geq K\} \end{aligned} \quad (29)$$

where I denotes an indicator function. Using the linear property of pricing we thus obtain

$$\Pi_t[X] = \Pi_t[S_T \cdot I\{S_T \geq K\}] - K \cdot \Pi_t[I\{S_T \geq K\}] \quad (30)$$

For the first term, we change to the measure Q^S having S as numeraire, and for the second term, we use the T -forward measure. Using the pricing formula (1) twice, once for each numeraire, we obtain the following basic option pricing formula, where we recognize the structure of the standard Black–Scholes formula.

Proposition 6 *Given the above-mentioned assumptions, the option price is given as*

$$\begin{aligned} \Pi_t[X] &= S_t Q^S(S_T \geq K | \mathcal{F}_t) \\ &\quad - K p(t, T) Q^T(S_T \geq K | \mathcal{F}_t) \end{aligned} \quad (31)$$

Notes

The first use of a numeraire different from the risk-free asset B was probably in [8] where, however,

the technique is not explicitly discussed. The first explicit use of a change of numeraire change was in [7], where an underlying stock was used as numeraire in order to value an exchange option. The numeraire change is also used in [4, 5] and basically in all later works on the existence of martingale measures in order to reduce the general case to the basic case of zero short rate. In these papers, the numeraire change as such is, however, not put to systematic use as an instrument for facilitating the computation of option prices in complicated models. In the context of interest rate theory, changes of numeraire were used and discussed independently in [2] and (within a Gaussian framework) in [6], where in both cases a bond maturing at a fixed time T is used as numeraire. A systematic study of general changes of numeraire can be found in [3]. For further examples of the change of numeraire technique see [1].

Utility Indifference Valuation

Under market frictions like illiquidity or transaction costs, contingent claims can incorporate some inevitable intrinsic risk that cannot be completely hedged away but remains with the holder. In general, they cannot be synthesized by dynamical trading in liquid assets and hence cannot be priced by no-arbitrage arguments alone. Still, an agent (she) can determine a valuation with respect to her preferences towards risk. The utility indifference value for a variation in the quantity of illiquid assets held by the agent is defined as the compensating variation of wealth, under which her maximal expected utility remains unchanged.

Consider an agent acting in a financial market with $d + 1$ liquid assets, which can be traded at market prices in a frictionless way anytime up to horizon $T < \infty$. In addition, there are J illiquid assets providing risky payouts $(B^j)_{j=1,\dots,J}$ at T . A preference order of the agent is described by an (indirect) utility function $u_t^b(x)$, describing the maximal expected utility obtainable when holding at t a position consisting of wealth $x \in \mathbb{R}$ invested in liquid assets (at market prices) and $b \in \mathbb{R}^J$ shares of illiquid assets. At time t , the agent prefers a position (x, b) to (x', b') if $u_t^b(x) \geq u_t^{b'}(x')$. She is indifferent if $u_t^b(x) = u_t^{b'}(x')$. The agent's *utility indifference (buy) value* for adding δ illiquid assets to her current position (x, b) is defined as the *compensating variation* $\pi_t^{b,x}(\delta)$ of her present wealth that leaves her utility unchanged, that is, as the solution to

$$u_t^{b+\delta}(x - \pi_t^{b,x}(\delta)) = u_t^b(x) \quad (1)$$

The *indifference sell value* is $-\pi_t^{b,x}(-\delta)$. In comparison, the *certainty equivalent* for adding δ to her position in illiquid assets is the *equivalent variation* $c_t^{b,x}(\delta)$ of the wealth that yields the same utility, that is, it is the solution to

$$u_t^b(x + c_t^{b,x}(\delta)) = u_t^{b+\delta}(x) \quad (2)$$

Equations (1), (2) have unique solutions if the functions $x \mapsto u_t^b(x)$ are strictly increasing and have the

same range for any b . The notion *compensating variation* is classical from the economic theory of demand by John Richard Hicks [7]. Alternatively, the terms *indifference value* (“price”) and *reservation price* have been used frequently in recent literature. We use the terms synonymously, but note that the classical terminology appears more accurate in reflecting the definition (1): in general, the compensating variation $\pi_t^{b,x}(\delta)$ is not a “price” for which δ illiquid assets can be traded in the market. Also, $\pi_t^{b,x}(\delta)$ is determined only at t in dependence of the position (x, b) prevailing and the variation δ occurring at the same time t ; it should not be interpreted prematurely as a “value at t ” that could be attributed at times before t to the payoff δB at T .

Next, we introduce the setup for a market model in which a family of utility functions u_t , $t \leq T$, is to be obtained. For simplicity, we consider a finite probability space $(\Omega, \mathcal{F}, P)$. For time $t \in \{0, \dots, T\}$ being discrete, the information flow is described by a filtration $(\mathcal{F}_t)_{0 \leq t \leq T}$ (see **Filtrations**), that is defined by refining partitions $\mathcal{A}_t$ of Ω and corresponds to a nonrecombining tree (see **Arrow–Debreu Prices**, Figure 1). The smallest nonempty events of $\mathcal{F}_t$ are called atoms $A \in \mathcal{A}_t$ of $\mathcal{F}_t$. Take $\mathcal{F}_0$ as trivial, $\mathcal{F}_T = \mathcal{F} = 2^\Omega$ as the set of all events, and all probabilities $P(\omega) > 0$, $\omega \in \Omega$ to be positive. Random variables X_t known at time t are denoted by $X_t \in L_{\mathcal{F}_t}$. They are determined by their values on each atom $A \in \mathcal{A}_t$, and can be identified with elements of a suitable $\mathbb{R}^N$. A process $(X_t)_{t \leq T}$ is adapted if $X_t \in L_{\mathcal{F}_t}$ for any t . Inequalities and properties stated for random variables and functions are meant to hold for all outcomes (coordinates). Conditional expectations with respect to $\mathcal{F}_t$ are denoted by $E_t[\cdot]$. For a family $\{X_t^a\} \subset L_{\mathcal{F}_t}(\mathbb{R})$, the random variable $\text{ess sup}_a X_t^a$ takes the value $\sup_a X_t^a(A)$ on atom $A \in \mathcal{A}_t$.

The price evolution of d liquidly traded risky assets is described by an $\mathbb{R}^d$ -valued adapted process $(S_t)_{0 \leq t \leq T}$. All prices are expressed in units of a further liquid riskless asset (unit of account) whose price is constant at 1. If, for example, the unit of account is the zero-coupon bond with maturity T , all prices are expressed in T -forward units. A trading strategy $(\vartheta_t)_{t \leq T} \in \Theta$ is described by the numbers of liquid assets $\vartheta_t \in L_{\mathcal{F}_{t-1}}$ to be held over any period $[t - 1, t)$. Its gains from t until T are $\int_t^T \vartheta \, dS := \sum_{k=t+1}^T \vartheta_k \Delta S_k$, with $\Delta S_k := S_k - S_{k-1}$. Any $X_T \in L_{\mathcal{F}_T}$ of the form $X_T = x + \int_t^T \vartheta \, dS$ represents a

wealth at time T that is attainable from $x \in L_{\mathcal{F}_t}$ at t by trading. Let $\mathcal{X}_T(x, t)$ denote the set of all such X_T , and set $\mathcal{X}_t(x) := \mathcal{X}_t(x, t-1)$. In addition to the liquid assets, there exist J illiquid assets delivering payoffs $B = (B^j)_{1 \leq j \leq J} \in L_{\mathcal{F}_T}(\mathbb{R}^J)$ at T . A quantity $b \in \mathbb{R}^J$ of illiquid assets provides at T the payoff $bB := \sum_j b^j B^j$. We assume that the market is free of arbitrage in the sense that the set $\mathcal{M}^e$ of equivalent probability measures Q under which S is a martingale (see **Martingales**) is nonempty. This is equivalent to assuming that all sets $\mathcal{D}_{s,t}$, $s < t \leq T$, of conditional state-price densities are nonempty. Technically, $\mathcal{D}_{s,t}$ is the set of strictly positive $D_{s,t} \in L_{\mathcal{F}_t}$ satisfying $E_s[D_{s,t}] = 1$ and $E_s[D_{s,t} \int_s^t \vartheta dS] = 0$ for all $\vartheta \in \Theta$. For brevity, let $\mathcal{D}_t := \mathcal{D}_{t-1,t}$. State-price densities are related to the likelihood density process $Z_t = E_t[dQ/dP]$ of a $Q \in \mathcal{M}^e$ by $D_{s,t} = Z_t/Z_s$.

Conditional Utility Functions and Dual Problems

Our agent's objective is to maximize her expected utility (3) of wealth at T for a direct utility function U , which is finite, differentiable, strictly increasing, and concave on all of $\mathbb{R}$, with $\lim_{x \rightarrow -\infty} U'(x) = \infty$ and $\lim_{x \rightarrow \infty} U'(x) = 0$. Holding position $(x, b) \in \mathbb{R} \times \mathbb{R}^J$ in liquid and illiquid assets at $t \leq T$, she maximizes

$$\begin{aligned} u_t^b(x) &:= \operatorname{ess\,sup}_{X_T \in \mathcal{X}_T(x,t)} E_t[U(X_T + bB)] \\ &= \operatorname{ess\,sup}_{X_T \in \mathcal{X}_T(x,t)} E_t[u_T^b(X_T)] \end{aligned} \quad (3)$$

We call $u_t^b(x)$ *u-regular* if (for all b, ω) the function $x \mapsto u_t^b(x)$ is strictly concave, increasing, and continuously differentiable on $\mathbb{R}$ with $\lim_{x \rightarrow -\infty} u_t^b(x) = +\infty$ and $\lim_{x \rightarrow +\infty} u_t^b(x) = 0$. For $t = T$, $u_T^b(x) = U(x + bB)$ satisfies the condition

$$\begin{aligned} u_t^b(x) &\text{ is } u\text{-regular, concave, and differentiable} \\ &\text{ in } (x, b), \text{ with } u_t^b(\mathbb{R}) = U(\mathbb{R}) \end{aligned} \quad (4)$$

with $U(\mathbb{R}) = \{U(x) : x \in \mathbb{R}\}$ denoting the range of U . The primal problems (3) are related, see A1–3, to the dual problems

$$v_t^b(y) := \operatorname{ess\,inf}_{D_{t,T} \in \mathcal{D}_{t,T}} E_t[V^b(yD_{t,T})], \quad y > 0 \quad (5)$$

for the conjugate function

$V^b(y) := \operatorname{ess\,sup}_x (U(x + bB) - xy)$ ($y > 0$, $b \in \mathbb{R}^J$), with $V^b(y) = V^0(y) + ybB$ and $v_T^b(y) = V^b(y)$. For later arguments, we assume the following:

(A1) $u_t^b(x)$ satisfies condition (4) for any t, b , and the value functions are conjugate:

$$v_t^b(y) = \operatorname{ess\,sup}_{x \in \mathbb{R}} (u_t^b(x) - xy), \quad y > 0 \quad (6)$$

$$u_t^b(x) = \operatorname{ess\,inf}_{y > 0} (v_t^b(y) + xy), \quad x \in \mathbb{R} \quad (7)$$

(A2) For any $t \leq T$ and $b, x, y \in L_{\mathcal{F}_{t-1}}$, there exist unique $\widehat{X}_t^b(x)$ and $\widehat{D}_t^b(y)$ that attain the single-period optima (8) and (9)

$$\begin{aligned} u_{t-1}^b(x) &= \operatorname{ess\,sup}_{X_t \in \mathcal{X}_t(x,t-1)} E_{t-1}[u_t^b(X_t)] \\ &= E_{t-1}[u_t^b(\widehat{X}_t^b(x))] \end{aligned} \quad (8)$$

$$\begin{aligned} v_{t-1}^b(y) &= \operatorname{ess\,inf}_{D_t \in \mathcal{D}_t} E_{t-1}[v_t^b(yD_t)] \\ &= E_{t-1}[v_t^b(y\widehat{D}_t^b(y))] \end{aligned} \quad (9)$$

and satisfy $u_t^b(\widehat{X}_t^b(x)) = y\widehat{D}_t^b(y)$ for x and y being related by $u_{t-1}^b(x) = y$.

(A3) For $t \leq T$, $b, x, y \in L_{\mathcal{F}_t}$, unique optima $\widehat{X}_T^b$ and $\widehat{D}_{t,T}^b$ for the multiperiod problems (3), (5) are attained, and can be constructed by dynamical programming $\widehat{X}_k^b = \widehat{X}_k^b(\widehat{X}_{k-1}^b)$ and $\widehat{D}_{t,k}^b = \widehat{D}_{t,k-1}^b \widehat{D}_k^b(y\widehat{D}_{t,k-1}^b)$ for $t < k \leq T$, with $\widehat{D}_k^b(\cdot)$ and $\widehat{X}_k^b(\cdot)$ from A2 and $\widehat{X}_t^b := x$ and $\widehat{D}_{t,t}^b := 1$. The optima satisfy $u_k^b(\widehat{X}_k^b) = y\widehat{D}_{t,k}^b$, $t < k \leq T$, for x and y being related by $u_t^b(x) = y$.

Ω being finite, A1–3 can be shown by convex duality; by arguments as in [21] follows inductively that A1–3 hold for $t-1$ on each atom, given they hold at t . Also see **Convex Duality** and **Second Fundamental Theorem of Asset Pricing**. Let us just mention here that, under regularity, the transforms (7) and (6) are inversions of each other, and $-v_t^b(y)$ is the inverse function of the marginal utility $u_t^b(x) = \frac{\partial}{\partial x} u_t^b(x)$.

Properties of Utility Indifference Values

Concavity (Convexity)

By concavity of U , indifference buy (sell) values $\pi_t^{b,x}(\delta)$ (respectively $-\pi_t^{b,x}(-\delta)$) are concave (convex) with respect to the quantity δ of illiquid assets

that they compensate for, that is,

$$\begin{aligned} & \lambda \pi_t^{b,x}(\delta^1) + (1 - \lambda) \pi_t^{b,x}(\delta^2) \\ & \leq \pi_t^{b,x}(\lambda \delta^1 + (1 - \lambda) \delta^2) \quad \text{for } \lambda \in [0, 1] \end{aligned} \quad (10)$$

Monotonicity

Monotonicity of U implies, on any atom $A \in \mathcal{A}_t$, that

$$\begin{aligned} 1_A \pi_t^{b,x}(\delta) & \leq 1_A \pi_t^{b,x}(\delta') \quad \text{if } 1_A \delta B \leq 1_A \delta' B \\ & \text{for } \delta, \delta' \in \mathbb{R}^J \end{aligned} \quad (11)$$

and that $1_A \pi_t^{b,x}(\delta) = 0$ holds if $1_A \delta B = 0$.

Dynamic consistency with no arbitrage

So far, we took the agent to trade optimally in liquid assets, while holding a fixed position b in illiquid assets. Now, suppose that she is ready to buy (or sell) at her compensating variations shares of illiquid assets in quantities as requested by another agent (he), dynamically over time. Let $\beta_t - \beta_0 \in L_{\mathcal{F}_{t-1}}(\mathbb{R}^J)$ denote the cumulative position in illiquid assets she has accepted until date $t - 1$, when she initially has held $\beta_0 := b \in \mathbb{R}^J$. At $t - 1 < T$, he chooses to sell $\Delta \beta_t \in L_{\mathcal{F}_{t-1}}(\mathbb{R}^J)$ illiquid assets. Given $\widehat{X}_{t-1}$ is the wealth in liquid assets she arrived with at $t - 1$, paying compensating variation changes her liquid wealth to $\widetilde{X}_{t-1} := \widehat{X}_{t-1} - \pi_{t-1}^{\beta_{t-1}, \widehat{X}_{t-1}}(\Delta \beta_t)$ such that the utility of her position stays equal $u_{t-1}^{\beta_{t-1}}(\widehat{X}_{t-1}) = u_{t-1}^{\beta_t}(\widetilde{X}_{t-1})$. Investing optimally for the next period according to A2 from her new position $(\widetilde{X}_{t-1}, \beta_t)$ (without knowing his future $(\beta_{t+k})_{k \geq 1}$), she arrives at t with liquid wealth

$$\begin{aligned} \widehat{X}_t &= \widehat{X}_t^{\beta_t}(\widetilde{X}_{t-1}) \\ &=: \widehat{X}_{t-1} - \pi_{t-1}^{\beta_{t-1}, \widehat{X}_{t-1}}(\Delta \beta_t) + \int_{t-1}^t \widehat{\vartheta} dS \end{aligned} \quad (12)$$

for an optimal strategy $\widehat{\vartheta}$ over $(t - 1, t]$. Given an initial wealth $\widehat{X}_0 = x \in \mathbb{R}$, the wealth process $\widehat{X}_t$ is determined by compensating variations and A2 such that $(u_t^{\beta_t}(\widehat{X}_t))$ is a martingale. Trading against indifference valuations but not following strategy $\widehat{\vartheta}$ would result in a suboptimal wealth process X_t for which the utility process $(u_t^{\beta_t}(X_t))$ is a supermartingale, therefore decreasing in the mean. By accepting to trade illiquid assets against her indifference values, she is not offering arbitrage

opportunities to her counterparty. Indeed, a strategy $\theta \in \Theta$ would offer arbitrage profits to him, jointly with (β_t) , if his gains

$$\begin{aligned} G_T &:= \int_0^T \theta dS \\ &+ \sum_{t=1}^T \pi_{t-1}^{\beta_{t-1}, \widehat{X}_{t-1}}(\Delta \beta_t) - (\beta_T - b)B \end{aligned} \quad (13)$$

satisfy $G_T \geq 0$ and $P[G_T > 0] > 0$. Unwinding her illiquid asset position at T , leaves her with final wealth

$$\begin{aligned} \widehat{X}_T &= x + \int_0^T \widehat{\vartheta} dS \\ &- \sum_{t=1}^T \pi_{t-1}^{\beta_{t-1}, \widehat{X}_{t-1}}(\Delta \beta_t) + \beta_T B \end{aligned} \quad (14)$$

Adding equation (13) to equation (14), would imply $E[u_T^b(x + \int_0^T \theta + \widehat{\vartheta} dS)] > E[u_T^b(\widehat{X}_T)] = u_0^b(x)$, contradicting definition (3).

Static no-arbitrage bounds

In particular, there is no arbitrage from buy(sell)-and-hold strategies in illiquid assets. For $x \in \mathbb{R}$, $b, \delta \in \mathbb{R}^J$ it thus holds

$$\begin{aligned} \pi_t^{b,x}(\delta) &\leq \text{ess sup}_{Q \in \mathcal{M}^e} E_t^Q[\delta B] \\ \text{and} \quad -\pi_t^{b,x}(-\delta) &\geq \text{ess inf}_{Q \in \mathcal{M}^e} E_t^Q[\delta B] \end{aligned} \quad (15)$$

For replicable payoffs $B^j = B_t^j + \int_t^T \vartheta^{B^j} dS$ with ϑ^{B^j} in Θ for all j , $B_t \in L_{\mathcal{F}_t}(\mathbb{R}^d)$ the indifference value $\pi_t^{b,x}(\delta)$ equals the replication cost (market price) δB_t .

Marginal indifference values

In general, $\pi_t^{b,x}(\delta)$ is nonlinear in δ . Since $\varepsilon \mapsto u_t^{b+\varepsilon\delta}(x - \pi_t^{b,x}(\varepsilon\delta))$ is constant, it holds

$$\left. \frac{\partial}{\partial \varepsilon} \pi_t^{b,x}(\varepsilon\delta) \right|_{\varepsilon=0} = \frac{\text{grad}_b u_t^b(x)}{u_t^b(x)} \delta \quad (16)$$

Hence, *marginal indifference values*, that is, compensating variations for infinitesimal changes of quantities, are linear in δ and given by the ratio of the gradient of $u_t^b(x)$ with respect to b and the marginal utility of wealth $u_t^b(x)$. The principle of valuation at ratios of marginal utilities is classical in economics, see for example [4]. Marginal indifference values can be computed from optimizers of the dual problem. They coincide with prices of an arbitrage-free dynamical price process in an enlarged market, where previously illiquid assets are tradable at “shadow” price processes, which are such that the utility maximizing agent is not trading those assets. To see this for $t = 0$, fix x, b . For y and $\widehat{D}_{0,T}^b$ from A3, let $R_k := E_k^Q[B]$, $k \leq T$, for $dQ := \widehat{D}_{0,T}^b dP$. Let $\bar{u}_0^b(x)$, $\bar{v}_0^b(y)$ be the primal and dual value functions (cf. equations (3),(5)) of the market $\bar{S} = (S, R)$ that is enlarged by the additional price process R . The set of state-price densities for the enlarged market is smaller, but includes the minimizer for equation (5). Hence $\bar{v}_0^b(\cdot) \geq v_0^b(\cdot)$ and $\bar{v}_0^b(y) = v_0^b(y)$, implying $\bar{v}_0^b(y) = v_0^b(y)$ and $\bar{u}_0^b(x) = u_0^b(x)$ by A1. Thus, the optimal strategy in the enlarged market is not trading the additional asset at the shadow price process (R_t) . The agent is, in particular, indifferent to infinitesimal initial variations of his position at shadow prices. Hence, R_0 must be given by the ratio in (16) of marginal utilities at $t = 0$. If the agent is taken to be representative for the whole market, holding a net supply of b illiquid assets, then (R_t) could be interpreted as a partial equilibrium price process.

Numeraire dependence

In general, utility indifference values depend on the utility functions and the numeraire (unit of account) with respect to which they are defined. But it is possible to choose state-dependent utility functions with respect to another numeraire such that indifference values (and optimal strategies) become numeraire invariant. Let (N_t) be the price process of a tradable numeraire, that is, $N_t = N_0 + \int_0^t \vartheta^N dS$ for $t \leq T$, $\vartheta^N \in \Theta$, with $N > 0$. Then indifference values coincide, that means $\pi_{t,N}^{b,x}(\delta) = \pi_t^{b,xN_t}(\delta)/N_t$ holds, if utilities and payoffs with respect to N satisfy the relations $u_{t,N}^b(x) = u_t^b(xN_t)$ (for $t = T$, hence all t) and $B_N := B/N_T$. Likewise, for numeraires $N, \tilde{N}$, the relations should be $u_{t,\tilde{N}}^b(x) = u_t^b(x\tilde{N}_t/N_t)$ and $B_{\tilde{N}} = B_N N_T / \tilde{N}_T$.

Partial hedging

Compensating variations can be associated with a utility-based hedging strategy, which, for an aggregate position (x, b) at $t = 0$, is defined as the strategy whose wealth process is $\widehat{X}_t^b(x) - \widehat{X}_t^0(x + c_0^{0,x}(b))$, for optimal wealth processes $\widehat{X}^b, \widehat{X}^0$ from A3 and $c_0^{0,x}(b)$ from equation (2). The risk that remains under partial hedging can be substantial, see the example below.

Case of Exponential Utility

Much of the literature on indifference pricing deals with exponential utility $U(x) = -\frac{1}{\alpha} \exp(-\alpha x)$ of constant absolute risk aversion $\alpha > 0$. Because U factorizes, the utility functions are of the form $u_t^b(x) = -\frac{1}{\alpha} e^{-\alpha(x+C_t^b)}$, $t \leq T$, for random variables $C_t^b \in L_{\mathcal{F}_t}$ not depending on x , with $C_T^b = bB$. Clearly, $\pi_t^{b,x}(\delta) = C_t^{b+\delta} - C_t^b$ does not depend on x , and the compensating variation (1) and the equivalent variation (2) coincide for exponential utility. From the dual value functions $v_t^b(y) = \frac{y}{\alpha} (\log y - 1 + \alpha C_t^b)$ from equation (5), one obtains a general formula

$$\begin{aligned} \pi_t^{0,x}(\delta) = & \operatorname{ess\,inf}_{D \in \mathcal{D}_{t,T}} \left\{ E_t[D(\delta B)] \right. \\ & \left. + \frac{1}{\alpha} (E_t[D \log D] - E_t[\widehat{D}_{t,T}^0 \log \widehat{D}_{t,T}^0]) \right\} \end{aligned} \quad (17)$$

for the indifference value $\pi_t^{b,x}(\delta) = \pi_t^{0,x}(\delta + b) - \pi_t^{0,x}(b)$, where $\widehat{D}_{t,T}^0$ is the minimizer of equation (5) for $b = 0$ that satisfies $E_t[\widehat{D}_{t,T}^0 \log \widehat{D}_{t,T}^0] = \operatorname{ess\,inf}_{D_{t,T}} E_t[D_{t,T} \log D_{t,T}]$. By equation (17), utility indifference sell values $\delta B \mapsto -\pi_t^{b,x}(-\delta)$ are monotonic in α , and satisfy the properties of convexity, translation invariance, and monotonicity, that constitute a *convex risk measure* (see **Convex Risk Measures**).

Under particular model assumptions, indifference values $\pi_t^{0,x}(\delta)$ can be computed by a backward induction scheme

$$\begin{aligned} & -\pi_{t-1}^{0,x}(\delta) \\ & = E_{t-1}^{Q^0} \left[\frac{1}{\alpha} \log E_{\mathcal{G}_t} [\exp(-\alpha \pi_t^{0,x}(\delta))] \right] \end{aligned} \quad (18)$$

starting from $\pi_T^{0,x}(\delta) = \delta B$. Roughly speaking, the assumptions needed comprise certain independence conditions plus semicompleteness of the market at each period. The scheme (18) has intuitive appeal, in showing that the indifference valuation is computed here by intertwining two well-known valuation methods: First, one takes an exponential certainty equivalent with respect to nontradable risk at the inner expectation (with $\mathcal{F}_{t-1} \subset \mathcal{G}_t \subset \mathcal{F}_t$); after that one takes a risk-neutral expectation of this certainty equivalent at the outer expectation (under the **minimal entropy martingale measure**), where, $\mathcal{G}_t$ -risk is taken as replicable from $t - 1$. See [1, 18] for precise technical assumptions and examples.

Example in Continuous Time

For an instructive example, consider a (nonfinite) filtered probability space $(\Omega, (\mathcal{F}_t)_{t \leq T}, P)$ with Brownian motions (W_t) and $(\tilde{W}_t) = (\rho W_t + \sqrt{1 - \rho^2} W_t^\perp)$ correlated by $\rho \in [-1, 1]$. The price process of a single risky asset is $S_t = S_0 + \sigma(W_t + \lambda t)$ with $\lambda, S_0 \in \mathbb{R}$, $\sigma > 0$, as in the model by **Louis Bachelier**. The illiquid asset's payout $B := Y_T$ for $Y_t = Y_0 + \tilde{\sigma}(\tilde{W}_t + \lambda t)$ can be interpreted as position in a nontraded but correlated asset. Trading strategies $\vartheta \in \Theta$ are taken to be adapted and bounded. The maximal expected exponential utilities

$$u_t^b(x) = -\frac{1}{\alpha} \exp \left(-\alpha \left(x + \frac{1}{2} \frac{\lambda^2}{\alpha} (T - t) + \pi_t^{0,x}(b) \right) \right), \quad x, b \in \mathbb{R} \quad (19)$$

are then attained by the optimal strategies $\hat{\vartheta}^b = \frac{\lambda}{\sigma\alpha} - b \frac{\sigma}{\sigma} \rho$, with

$$\pi_t^{0,x}(b) = bY_t + b\tilde{\sigma}(\tilde{\lambda} - \lambda\rho)(T - t) - \frac{1}{2} \alpha b^2 \tilde{\sigma}^2 (1 - \rho^2)(T - t) \quad (20)$$

Indifference values $\pi_t^{b,x}(\delta) = \pi_t^{0,x}(b + \delta) - \pi_t^{0,x}(b)$ for exponential utility do not depend on wealth x . Optimality of equation (19) and $\hat{\vartheta}^b$ follows by noting that $u_t^b(\int_0^t \vartheta \, dS)$ is a martingale for $\vartheta = \hat{\vartheta}^b$ and a supermartingale for any other $\vartheta \in \Theta$. Clearly, indifference buy (sell) values $\pi_t^{b,x}(\delta)$ (respectively $-\pi_t^{b,x}(-\delta)$) are decreasing (increasing) in the risk aversion α . They are linear in the quantity δ only if correlation is perfect ($|\rho| = 1$). Then, they coincide

with the replication cost of δB . Marginal utility indifference values are given by

$$\frac{\partial}{\partial \delta} \pi_t^{b,x}(\delta) = Y_t + \tilde{\sigma}(\tilde{\lambda} - \lambda\rho)(T - t) - \alpha(b + \delta)\tilde{\sigma}^2(1 - \rho^2)(T - t) \quad (21)$$

Under the (minimal entropy) martingale measure $dQ^0 = \exp(-\lambda W_T - \lambda^2 T/2) dP$ we have $S_t = S_0 + \sigma W_t^0$ for independent Q^0 -Brownian motions (W_t^0) and $(W_t^\perp)$. Indifference values can be expressed by

$$-\pi_t^{0,x}(b) = \frac{1}{\alpha(1 - \rho^2)} \log E_t^{Q^0} [\exp(\alpha(1 - \rho^2)(-bB))] \quad (22)$$

Formulas like equation (22) have also been obtained for different models, including the case where the price processes of the risky and the nontraded asset (underlying of B) are given by correlated geometric Brownian motions, see [6, 16].

To discuss the possible size of the partial hedging error, let $S_0, Y_0, \lambda, \tilde{\lambda}$ be zero, $T = 1$, and $\sigma = \tilde{\sigma}$. We assume that the agent has accepted initially an illiquid position b at her indifference valuation. Her utility-based partial hedging strategy when holding b illiquid assets is $\hat{\vartheta}^b - \vartheta^0 = -b\rho$. Her hedging error $H = -\pi_0^{0,x}(b) + bB - b\sigma\rho W_1^0 = \frac{1}{2}\alpha b^2 \sigma^2 (1 - \rho^2) + b\sigma\sqrt{1 - \rho^2} W_1^\perp$ is normally distributed. Its standard deviation accounts for $\sqrt{1 - \rho^2} \times 100\%$ of that for the unhedged payoff $bB = bY_T$. For correlation $\rho = 80\%$, for example, the error size is still substantial at a ratio of 60%. Even for $\rho = 99\%$, it is still above 14%. To be compensated for the remaining risk in terms of her expected utility, the agent requires $-\pi_0^{0,x}(b) = \frac{1}{2}\alpha b^2 \sigma^2 (1 - \rho^2)$ at $t = 0$. Her compensating variation of wealth is proportional to the variance of H and to her risk aversion α .

Further Reading

To value options under transaction costs, indifference valuation was applied in [8]. The method is not limited to European payoffs. For payoffs with optimal exercise features, see [10, 17]. Indifference values for payoff streams could be defined by equation (1) for utilities that reflect preferences on future payment streams, like in [22]. For results on nonexponential

utilities, see [5, 12, 14]. For performance of utility-based hedging strategies, see [15]. Besides dynamical programming and convex duality, solutions have been obtained by backward stochastic differential equations (see **Backward Stochastic Differential Equations**) [10, 13, 20], also for non-convex closed constraints [9] and jumps [2]. For asymptotic results on valuation and hedging for small volumes, see [2, 5, 12, 13]. A Paretian equilibrium formulation for indifference pricing has been presented in [11]. Being nonlinear, indifference values can reflect diversification or accumulation of risk for applications areas like real options or insurance, see [6, 14, 19, 22]; but modeling and computation are more demanding, since a portfolio of assets cannot be valued by parts in general. Instead, each component is to be judged by its contribution to the overall portfolio. More comprehensive references are given in [1, 3, 4, 6, 16].

Superhedging

Pricing and hedging of contingent claims are the two main problems of mathematical finance. They both have a clear and transparent solution when the underlying market model is complete, that is, for each contingent claim with promised payoff H there exists a self-financing admissible trading strategy whose wealth at maturity equals H (see **Complete Markets**). Such a strategy is called the *hedging strategy* of the contingent claim H . The smallest initial wealth that allows to reach H at maturity via admissible trading is called the *hedging price* of H .

Under a suitable no-arbitrage assumption (see **Fundamental Theorem of Asset Pricing**), the second fundamental theorem of asset pricing (see **Second Fundamental Theorem of Asset Pricing**) states that replicability of every contingent claim is equivalent to the uniqueness of the equivalent martingale measure $\mathbb{Q}$ (see **Equivalent Martingale Measures**).

It turns out that in a complete market (see **Complete Markets**), the hedging price at time $t = 0$ of a contingent claim H , denoted by $p(H)$, coincides with the expectation of discounted H under the unique equivalent martingale measure $\mathbb{Q}$, that is, $p(H) = \mathbb{E}_{\mathbb{Q}}[D_T H]$ where D_T is a discounting factor over $[0, T]$.

If the market model is incomplete, there exist contingent claims that are not perfectly replicable via admissible trading strategies. In other words, in such financial models, contingent claims are not redundant assets. Therefore, since perfect replicability cannot be always achieved, this requirement has to be relaxed. One way of doing this consists in introducing the concept of *superhedging*.

Given a contingent claim H with maturity $T > 0$, a superhedging strategy for H is an admissible trading strategy such that its terminal wealth V_T super-replicates H , that is, $V_T \geq H$. The superhedging price of H is the smallest initial endowment that allows an investor to super-replicate H at maturity; in other words, it is the initial value V_0 of the superhedging strategy of H .

Superhedging was introduced and investigated first by El Karoui and Quenez [13, 14] in a continuous-time setting where the risky assets follow a multidimensional diffusion process. Independently, Naik and Uppal [25] studied the same problem in a discrete-time model with finite set of scenarios and

noticed that, in the presence of leverage constraints, superhedging may be cheaper than perfect hedging. The same phenomenon has been observed by Benais *et al.* [1] in the presence of transaction costs.

The characterization of superhedging strategies and prices is the object of a family of results called *superhedging theorems*.

Superhedging Theorems

A large literature has been devoted to characterizing the set of all initial endowments that allows to superhedge a contingent claim H as a first crucial step to compute the superhedging price, the infimum of that set. In this article, we focus essentially on continuous-time hedging of European options, that is, with a fixed exercise time T , and distinguish between two cases: frictionless incomplete markets and markets with frictions. For superhedging in discrete-time models and for American options, the interested reader could see respectively Föllmer and Schied's book [17] and **American Options**.

Frictionless Incomplete Markets

To facilitate the discussion, let us fix the notation first. We consider a market model composed of $d \geq 1$ risky assets whose discounted price dynamics is described by a càdlàg and locally bounded semimartingale $S = (S_t)_{t \in [0, T]}$, where $T > 0$ is a given finite time horizon. S is defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and adapted to a filtration $(\mathcal{F}_t)_{t \in [0, T]}$ with $\mathcal{F}_t \subset \mathcal{F}$ for all $t \leq T$ satisfying usual conditions. Notice that prices S are already discounted; this is equivalent to assuming that the spot interest rate $r = 0$. This model is, in general, incomplete, that is, it may admit infinitely many equivalent martingale measures (see **Equivalent Martingale Measures**).

Let H be a positive $\mathcal{F}_T$ -measurable random variable, modeling the final payoff of a given contingent claim, for example, $H = (S_T - K)^+$, a European call option written on S , with maturity T and strike price $K > 0$.

An admissible trading strategy is a couple (x, θ) where $x \in \mathbb{R}$ is an initial endowment and $\theta = (\theta_t)_{t \in [0, T]}$ a predictable S -integrable process, such that the corresponding wealth $V_t^{x, \theta} = x + \int_0^t \theta_u dS_u \geq -a$ for every $t \in [0, T]$ and for some threshold $a > 0$. We denote $\mathcal{A}$ as the set of all admissible strategies.

Definition 1 Let $H \geq 0$ be a given contingent claim. $(x, \theta) \in \mathcal{A}$ is a superhedging strategy for H if $V_T^{x, \theta} \geq H$ $\mathbb{P}$ -a.s. (almost surely). Moreover, the superhedging price $\bar{p}(H)$ of H is given by

$$\bar{p}(H) = \inf \left\{ x \in \mathbb{R} : \exists (x, \theta) \in \mathcal{A}, V_T^{x, \theta} \geq H \text{ a.s.} \right\} \quad (1)$$

The fundamental result in the literature on superhedging is the dual characterization of the set $\mathcal{D}^H$ of all initial endowments $x \in \mathbb{R}$ leading to superhedge H . In an incomplete frictionless market, the relevant dual variables are the densities of all equivalent martingale measures $d\mathbb{Q}/d\mathbb{P}$. We denote $\mathcal{M}^e$ as the set of all equivalent (local) martingale measures for S . In this setting, the superhedging theorem states that

$$\mathcal{D}^H = \{x \in \mathbb{R} : \mathbb{E}_{\mathbb{Q}}[H] \leq x, \forall \mathbb{Q} \in \mathcal{M}^e\} \quad (2)$$

An important consequence of equation (2) is that the superhedging price $\bar{p}(H)$ satisfies

$$\bar{p}(H) = \sup_{\mathbb{Q} \in \mathcal{M}^e} \mathbb{E}_{\mathbb{Q}}[H] \quad (3)$$

While an advantage of superhedging is that it is preference free, from the previous characterization of $\bar{p}(H)$ as the biggest expectation $\mathbb{E}_{\mathbb{Q}}[H]$ over all equivalent martingale measures, it becomes apparent that pursuing a superhedging strategy can be too expensive, depending on the financial model and on the constraints on portfolios. This is the main disadvantage of such a criterion, which is, nonetheless, of great interest as a benchmark. Moreover, for an agent with a large risk aversion and under transaction costs (see the section Markets with Frictions), the reservation price approaches the superhedging price, as established in [2].

El Karoui and Quenez [13, 14] first proved the superhedging theorem in an Itô's diffusion setting and Delbaen and Schachermayer [10, 11] generalized it to, respectively, a locally bounded and unbounded semimartingale model, using a Hahn–Banach separation argument.

The superhedging theorem can be extended in order to characterize the *dynamics* of the minimal superhedging portfolio of a contingent claim H , that is, the cheapest at any time t of all superhedging portfolios of H with the same initial

wealth. This extension is a consequence of the so-called *optional decomposition of supermartingales*. The optional decomposition was first proved in [13, 14] for diffusions and then extended to general semimartingales by Kramkov [24], Föllmer and Kabanov [15], and Delbaen and Schachermayer [12]. This is a very deep result of the general theory of stochastic processes and roughly states that any càdlàg-positive $\mathbb{Q}$ -supermartingale X , for any $\mathbb{Q} \in \mathcal{M}^e$, can be decomposed as follows:

$$X_t = X_0 + \int_0^t \theta_u dS_u - C_t, \quad t \in [0, T] \quad (4)$$

where θ is a predictable, S -integrable process and C an increasing optional process, to be interpreted as a cumulative consumption process. What is remarkable is that the local martingale part can be represented as a stochastic integral with respect to S so that it is a local martingale under any equivalent martingale measure $\mathbb{Q}$. In this sense, decomposition (4) is universal. The price to pay is that the increasing process C is, in general, not predictable as in the Doob–Meyer decomposition (see **Doob–Meyer Decomposition**) but only optional. The process C has the economic interpretation of cumulative consumption.

The decomposition (4) implies that the wealth dynamics of the minimal superhedging portfolio for a contingent claim H is given by

$$V_t = \text{ess sup}_{\mathbb{Q} \in \mathcal{M}^e} \mathbb{E}_{\mathbb{Q}}[H | \mathcal{F}_t], \quad t \in [0, T] \quad (5)$$

An analogous result holds for American contingent claims too (see [13–15, 24] for details at increasing levels of generality).

Finally, in the more specific setting of stochastic volatility models, Cvitanic *et al.* [8] compute the superhedging strategy and price for a contingent claim $H = g(S_T)$, yielding that the former is a buy-and-hold strategy and so the latter is just S_0 . The same study is carried over under portfolio constraints.

Markets with Frictions

In the previous section, we made the implicit assumption that investors can trade in continuous time and without frictions. This is clearly a strong idealization of the real world; that is why during the last 15 years much effort has been devoted to the superhedging approach under various types of trading constraints.

Transaction Costs. Financial models with proportional transaction costs were studied first by Jouini and Kallal [19] and then generalized in a series of papers by Kabanov and his coauthors [20–22].

For the reader's convenience, we briefly introduce the model, following the bid–ask matrix formalism introduced by Schachermayer [27], which is only one of many equivalent convenient ways of describing it (see, e.g., [22] and **Transaction Costs** for more details).

We consider an economy with $d \geq 1$ risky assets (e.g., foreign currencies); $\pi_t^{ij}(\omega)$ denotes the number of physical units of asset i that can be exchanged with 1 unit of asset j at time $t \in [0, T]$. All of them are assumed to be adapted to some filtration and càdlàg. An important role is played by the so-called *solvency region* $K_t(\omega)$, the cone generated by the unit vectors e^i and $\pi_t^{ij}e^i - e^j$ for $1 \leq i, j \leq d$. Elements of $K_t(\omega)$ are all the positions that can be liquidated into a portfolio with a nonnegative quantity of each currency. We denote $K_t^*(\omega)$ as the positive polar of $K_t(\omega)$.

A self-financing portfolio process is modeled by a d -dimensional finite variation process $V = (V_t)_{t \in [0, T]}$ such that each infinitesimal change $dV_t(\omega)$ lies in $-K_t(\omega)$, that is, a portfolio change at time t has to be done according to the trading terms described by the solvency cone K_t .

In this setting, so-called *strictly consistent price systems* play the same role as the equivalent martingale measures. A strictly consistent price system Z is a positive non-null d -dimensional martingale such that each $Z_t(\omega)$ belongs to the relative interior of $K_t^*(\omega)$ almost surely for all $t \in [0, T]$. We denote $\mathcal{Z}^s$ as the set of all strictly consistent price systems. A standard assumption is that there exists at least one of such Z 's, that is, $\mathcal{Z}^s \neq \emptyset$, which is equivalent to some kind of no-arbitrage condition (see **Transaction Costs** for details).

Let $H = (H^1, \dots, H^d)$ be a d -dimensional contingent claim such that $H + a\mathbf{1} \in K_T$ for some $a \in \mathbb{R}$. We say that an admissible^a portfolio V superhedges H if $V_T - H \in K_T$. Consider the set $\mathcal{D}^H$ of all initial endowment $x \in \mathbb{R}^d$ such that there exists an admissible portfolio V , $V_0 = x$, that superhedges H .

In this model, the superhedging theorem states that

$$\mathcal{D}^H = \{x \in \mathbb{R}^d : \mathbb{E}[Z_T H] \leq \langle x, Z_0 \rangle, \forall Z \in \mathcal{Z}^s\} \quad (6)$$

where $\langle \cdot, \cdot \rangle$ denotes the usual scalar product in $\mathbb{R}^d$. This theorem has been proven with increasing degree of generality by Cvitanić and Karatzas [7], Kabanov [20], and Kabanov and Last [21] for continuous bid–ask processes $(\pi_t)_{t \in [0, T]}$ and constant proportional transaction costs, by Kabanov and Stricker [22] under slightly more general assumptions and finally, motivated by a counterexample constructed by Rásonyi [26], Campi and Schachermayer [5] extend it to discontinuous π .

Explicit computations of the superhedging price have been performed in [3, 9, 18] for a European-type contingent claim $H = g(S_T)$, where S_T is the price at time T of a given asset in terms of some fixed numéraire. Under different assumptions, the superhedging strategy is a buy-and-hold one, so that the corresponding superhedging price is the price at time $t = 0$ of the underlying S_0 .

Finally, duality methods for American options under proportional transaction costs are briefly treated in **Transaction Costs**.

Other Types of Market Frictions. Superhedging has also been studied under other types of constraints on, for example, shortselling and/or borrowing (see, e.g., Cvitanić and Karatzas' paper [6] and Karatzas and Shreve's book [23], Chapter 5, for more details). Very often, an agent willing to superhedge a contingent claim H has to choose a strategy fulfilling a given set of constraints. Let us denote $\mathcal{A}_c$ as the class of constrained trading strategies. In this case, the constrained superhedging price $\bar{p}_c(H)$ is given by

$$\bar{p}_c(H) = \inf \left\{ x \in \mathbb{R}^d : \exists (x, \theta) \in \mathcal{A}_c, V_T^{x, \theta} \geq H \right\} \quad (7)$$

Cvitanić and Karatzas [6] gave the first dual characterization of $\bar{p}_c(H)$ in a diffusions setting, which was further generalized to general semimartingales by Föllmer and Kramkov [16] via a constrained version of the optional decomposition theorem, whose original version we already discussed at the end of the section Frictionless Incomplete Markets.

We conclude by mentioning a recent series of papers by Broadie *et al.* [4] and by Soner and Touzi [28, 29] on superhedging under *gamma constraints*, where an agent is allowed to hedge H , having at the same time a control on the gamma of his or her portfolios.

End Notes

^aWe remark *en passant* that the notion of admissibility in the presence of transaction costs, that we do not give here, is a subtle one. The interested reader could look at [5] for a short discussion.

LUCIANO CAMPI

Free Lunch

In the process of building realistic mathematical models of financial markets, absence of opportunities for riskless profit is considered to be a *minimal* normative assumption in order for the market to be in equilibrium state. The reason is quite obvious. If opportunities for riskless profit were present in the market, every economic agent would try to reap them. Prices would then instantaneously move in response to an imbalance between supply and demand. This sudden price movement would continue as long as opportunities for riskless profit are still present in the market. Therefore, in market equilibrium, no such opportunities should be possible.

The aforementioned simple and very natural idea has proved very fruitful and has lead to great mathematical as well as economical insight in the theory of quantitative finance. A rigorous formulation of the exact definition of “absence of opportunities for riskless profit” turned out to be a highly nontrivial fact that troubled mathematicians and economists for at least two decades.^a As the road unfolded, the valuable input of the theory of stochastic analysis in financial theory was obvious; in the other direction, the development of the theory of stochastic processes benefited immensely from problems that emerged purely from these financial considerations.

Since the late 1970s, there has been a notion that there is a deep connection between the absence of opportunities for riskless profit and the existence of a risk-neutral measure,^b that is, a probability that is equivalent to the original one under which the discounted asset price processes have some kind of martingale property. Existence of such measures are of major practical importance, since they open the road to pricing illiquid assets or contingent claims in the market (see **Risk-neutral Pricing**). The result of the above notion has been called the *fundamental theorem of asset pricing (FTAP)*; for a detailed account, see **Fundamental Theorem of Asset Pricing**.

The easiest and most classical way to formulate the notion of riskless profit is *via* the so-called *arbitrage strategy* (see **Arbitrage Strategy**). An arbitrage is a combination of positions in the traded assets that requires zero initial capital and results in non-negative outcome with a strictly positive probability of the wealth being strictly positive at a fixed time

point in the future (after liquidation has taken place). Naturally, the previous formulation of an arbitrage presupposes that a probabilistic model for the random movement of liquid asset prices has been set up. In [5], a discrete state space, multiperiod discrete-time financial market was considered. For this model, the authors showed the equivalence between the economical “no arbitrage” (NA) condition and the mathematical stipulation of existence of an equivalent probability that makes the discounted asset price processes martingales.

Crucial in the proof of the result in [5] was the separating hyperplane theorem in finite-dimensional Euclidean spaces. One of the convex sets to be separated is the class of all terminal outcomes resulting from trading and possible consumption starting from zero capital; the other is the positive orthant. The NA condition is basically the statement that the intersection of these two convex sets consists of only the zero vector.

After the publication of [5], a saga of papers followed that were aimed, one way or another, at strengthening the conclusion by considering more complicated market models. It quickly became obvious that the previous NA condition is no longer sufficient to imply the existence of a risk-neutral measure; it is too weak. In infinite-dimensional spaces, separation of hyperplanes, made possible by means of the geometric version of the Hahn–Banach theorem, requires the closedness of the set C of all terminal outcomes resulting from trading and possible consumption starting from zero capital. The simple NA condition does not imply this, in general. This has lead Kreps [7] to define a *free lunch* as a generalized, asymptotic form of an arbitrage.

Essentially, a free lunch is a possibly infinite-valued random variable f with $\mathbb{P}[f \geq 0] = 1$ and $\mathbb{P}[f > 0] > 0$ that belongs to the *closure* of C . Once an appropriate topology is defined on $\mathbf{L}^0$, the space of all random variables, in order for the last closure (call it $\tilde{C}$) to make sense, the “no-free-lunch” (NFL) condition states that^c $\tilde{C} \cap \mathbf{L}_+^0 = \{0\}$. Kreps [7] used this idea with a very weak topology on locally convex spaces and showed the existence of a *separating measure*.^d However, apart from trivial cases, this topology does not stem from a metric, which means that closedness cannot be described in terms of convergence of sequences. This makes the definition of a free lunch quite nonintuitive.

After [7], there were lots of attempts to introduce a condition closely related to NFL that would be more economically plausible, albeit still equivalent to NFL, and would prove equivalent to the existence of a risk-neutral measure. In general finite-horizon, discrete-time markets, it was shown in^e [1] that the plain NA condition is equivalent to NFL. This seemed to suggest the possibility of a nice counterpart of the NFL condition for more complicated models. Delbaen [2] treated the case of continuous time, bounded, and continuous asset prices and used a neat condition, equivalent to NFL, called^f *no free lunch with bounded risk* (NFLBR) that can be stated in terms of sequence convergence. Essentially, the NFLBR condition precludes asymptotic arbitrage at some fixed point in time, when the overall downside risk of all the wealth processes involved is bounded. Later, [8] treated the case of infinite-horizon discrete-time models, where the NFLBR condition was once again used. At this point, with the continuous-path and infinite-horizon discrete-time cases resolved, there seemed to be one more “gluing” step to reach a general version of the FTAP for semimartingale models. Not only did Delbaen and Schachermayer make this step for semimartingale models, they actually further weakened the NFLBR condition to the *no free lunch with vanishing risk* (NFLVR) condition, where the previous asymptotic arbitrage at some fixed point in time is precluded and the overall downside risk of all the wealth processes *tends to zero* in the limit. In more precise mathematical terms, the NFLVR condition can be stated as $\overline{C} \cap \mathbf{L}_+^0 = \{0\}$, where $\overline{C}$ is the closure in the very strong $\mathbf{L}^\infty$ -topology of (almost sure) uniform convergence.

The NFLVR condition was finally the one that proved itself to be the most fruitful in obtaining a general version of the FTAP; see [3] and [4] (also see **Fundamental Theorem of Asset Pricing**). It is both economically plausible and mathematically convenient. Needless to say, and like many great results in science, the final simplicity and clarity of the result’s statement came with the price that the corresponding proof was extremely technical.

End Notes

^aThe exact market viability definition is still sometimes the source of debate.

^bAlso called an *equivalent martingale measure*—see **Equivalent Martingale Measures** for an account of the different notions that the previous appellation encompasses.

^c $\mathbf{L}_+^0$ is the subset of $\mathbf{L}^0$ consisting of nonnegative random variables.

^dA separating measure is a probability $\mathbb{Q}$ equivalent to the original one such that all elements of C have nonpositive expectation with respect to $\mathbb{Q}$. In this context, also see **Fundamental Theorem of Asset Pricing**. Note that in the case of a continuous-time market model with locally bounded asset prices, a separating measure automatically makes the discounted asset prices *local* martingales. This was proved in [3].

^eFor a compact and rather elementary proof of this result, see [6].

^fThe appellation to this condition was actually coined by W. Schachermayer in [8].

CONSTANTINOS KARDARAS

Minimal Entropy Martingale Measure

Consider a stochastic process $S = (S_t)_{t \geq 0}$ on a probability space $(\Omega, \mathcal{F}, P)$ and adapted to a filtration $\mathcal{F} = (\mathcal{F}_t)_{t \geq 0}$. Each S_t takes values in $\mathbb{R}^d$ and models the discounted prices at time t of d basic assets traded in a financial market. An equivalent local martingale measure (ELMM) for S , possibly on $[0, T]$ for a time horizon $T < \infty$, is a probability measure Q equivalent to the original (historical, real-world) measure P (on $\mathcal{F}_T$, if there is a T) such that S is a local Q -martingale (on $[0, T]$, respectively); *see Equivalent Martingale Measures*. If S is a nonnegative P -semimartingale, the fundamental theorem of asset pricing says that the existence of an ELMM Q for S is equivalent to the absence-of-arbitrage condition (NFLVR) that S admits no free lunch with vanishing risk; *see Fundamental Theorem of Asset Pricing*.

Definition 1 Fix a time horizon $T < \infty$. An ELMM Q^E for S on $[0, T]$ is called *minimal entropy martingale measure (MEMM)* if Q^E minimizes the relative entropy $H(Q|P)$ over all ELMMs Q for S on $[0, T]$.

Recall that the *relative entropy* is defined as

$$H(Q|P) := \begin{cases} E_P \left[\frac{dQ}{dP} \log \frac{dQ}{dP} \right] & \text{if } Q \ll P \\ +\infty & \text{otherwise} \end{cases} \quad (1)$$

This is an example of the general concept of an *f-divergence* of the form

$$D_f(Q|P) := \begin{cases} E_P \left[f \left(\frac{dQ}{dP} \right) \right] & \text{if } Q \ll P \\ +\infty & \text{otherwise} \end{cases} \quad (2)$$

where f is a convex function on $[0, \infty)$; *see* [26, 49], or [22] for a number of examples. The minimizer $Q^{*,f}$ of $D_f(\cdot|P)$ is then called *f-optimal ELMM*.

In many situations arising in mathematical finance, *f*-optimal ELMMs come up *via* duality from expected utility maximization problems; *see Expected Utility Maximization: Duality Methods; Expected Utility Maximization*. One starts with a utility function U (*see Utility Function*) and obtains f (up to an affine function) as the convex conjugate

of U , that is,

$$f(y) - \alpha y - \beta = \sup_x (U(x) - xy) \quad (3)$$

Finding $Q^{*,f}$ is then the dual to the primal problem of maximizing the expected utility

$$\vartheta \mapsto E \left[U \left(x_0 + \int_0^T \vartheta_r dS_r \right) \right] \quad (4)$$

from terminal wealth over allowed investment strategies ϑ . Moreover, under suitable conditions, the solutions $Q^{*,f}$ and $\vartheta^{*,U}$ are related by

$$\frac{dQ^{*,f}}{dP} = \text{const. } U' \left(x_0 + \int_0^T \vartheta_r^{*,U} dS_r \right) \quad (5)$$

More details can, for instance, be found in [26, 41, 46, 67, 68]. Relative entropy comes up with $f_E(y) = y \log y$ when one starts with the exponential utility functions $U_\alpha(x) = -e^{-\alpha x}$ with risk aversion $\alpha > 0$. The duality in this special case has been studied in detail in [8, 18, 40].

Since f_E is strictly convex, the minimal entropy martingale measure is always unique. If S is locally bounded, the MEMM (on $[0, T]$) exists if and only if there is at least one ELMM Q for S on $[0, T]$ with $H(Q|P) < \infty$ [21]. For general unbounded S , the MEMM need not exist; [21] contains a counterexample, and [1] shows how the duality above will then fail. In [21], it is also shown that the MEMM is automatically equivalent to P , even if it is defined as the minimizer of $H(Q|P)$ over all P -absolutely continuous local martingale measures for S on $[0, T]$, provided that there exists some ELMM Q for S on $[0, T]$ with $H(Q|P) < \infty$. Moreover, the density of Q^E with respect to P on $\mathcal{F}_T$ has a very specific form; it is given by

$$\frac{dQ^E}{dP} \Big|_{\mathcal{F}_T} = Z_T^E = Z_0 \exp \left(\int_0^T \vartheta_r^E dS_r \right) \quad (6)$$

for some constant $Z_0 > 0$ and some predictable S -integrable process ϑ^E . This has been proved in [21] for models in finite discrete time and in [26, 28] in general; *see also* [23] for an application to finding optimal strategies in a Lévy process setting. Note,

however, that representation (2) holds only at the time horizon, T ; the density process

$$Z_t^E = \frac{dQ^E}{dP} \Big|_{\mathcal{F}_t} = E_P[Z_T^E | \mathcal{F}_t], \quad 0 \leq t \leq T \quad (7)$$

is usually quite difficult to find. We remark that the above results on both the equivalence to P and the structure of the f_E -optimal Q^E have versions for more general f -divergences [26]. (Essentially, equation (2) is relation (1) in the case of exponential utility, but it can also be proved directly without using general duality.)

The history of the minimal entropy martingale measure Q^E is not straightforward to trace. A general definition and an authoritative exposition are given by Frittelli [21]. However, the idea of the so-called mini-max measures to link martingale measures *via* duality to utility maximization already appears, for instance, in [30, 31, 41]; see also [8]. Other early contributors include Miyahara [53], who used the term “canonical martingale measure”, and Stutzer [70]; some more historical comments and references are contained in [71]. Even before, in [20], it was shown that the property defining the MEMM is satisfied by the so-called minimal martingale measure if S is continuous and the so-called mean-variance trade-off of S has constant expectation over all ELMMs for S ; see also **Minimal Martingale Measure**. The most prominent example for this occurs when S is a Markovian diffusion [53].

After the initial foundations, work on the MEMM has mainly concentrated on three major areas. The first aims to determine or describe the MEMM and, in particular, its density process Z^E more explicitly in specific models. This has been done, among others, for the following:

- stochastic volatility models: see [9, 10, 35, 62, 63], and compare also **Volatility; Barndorff-Nielsen and Shephard (BNS) Models**;
- jump-diffusions [54]; and
- Lévy processes (see **Lévy Processes**), both in general and in special settings: see [36] for an overview and [42, 43] for some examples. In particular, many studies have considered *exponential Lévy models* (see **Exponential Lévy Models**) where $S = S_0 \mathcal{E}(L)$ and L is a Lévy process under P . There, the existence of the MEMM Q^E reduces to an analytical condition on the Lévy triplet of L . Moreover, Q^E is then

given by an Esscher transform (see **Esscher Transform**) and L is again a Lévy process under Q^E ; see, for instance, [13, 19, 24, 39].

For continuous semimartingales S , an alternative approach is to characterize Z^E *via* semimartingale backward equations or backward stochastic differential equations [50, 52]. The results in [56, 57] use a mixture of the above ideas in a specific class of models.

The second major area is concerned with convergence questions. Several authors have proved, in several settings and with various techniques, that the minimal entropy martingale measure Q^E is the limit, as $p \searrow 1$, of the so-called p -optimal martingale measures obtained by minimizing the f -divergence associated to the function $f(y) = y^p$. This line of research was initiated in [27, 28], and later contributions include [39, 52, 65]. In [45, 60], this convergence is combined with the general duality (1) from utility maximization in order to obtain convergence results for optimal wealths and strategies as well.

The third, and by far the most important area of research on the MEMM, is centered on its link to the exponential utility maximization problem; see [8, 18] for a detailed exposition of this issue. More specifically, the MEMM is very useful when one studies the valuation of contingent claims by (exponential) *utility indifference valuation*; see **Utility Indifference Valuation**. To explain this, we fix an initial capital x_0 and a random payoff H due at time T . The maximal expected utility one can obtain by trading in S *via* some strategy ϑ , if one starts with x_0 and has to pay out H in T , is

$$\sup_{\vartheta} E \left[U \left(x_0 + \int_0^T \vartheta_r dS_r - H \right) \right] =: u(x_0; -H) \quad (8)$$

and the *utility indifference value* x_H is then implicitly defined by

$$u(x_0 + x_H; -H) = u(x_0; 0) \quad (9)$$

Hence, x_H represents the monetary compensation required for selling H if one wants to achieve utility indifference at the optimal investment behavior. If $U = U_\alpha$ is exponential, its multiplicative structure

makes the analysis of the utility indifference value x_H tractable, in remarkable contrast to all other classical utility functions. Moreover, $u(x_0; -H)$ as well as x_H and the optimal strategy ϑ_H^* can be described with the help of a minimal entropy martingale measure (defined here with respect to a new, H -dependent reference measure P_H instead of P). This topic has first been studied in [4, 58, 59, 64]; later work has examined intertemporally dynamic extensions [5, 51], descriptions *via* backward stochastic differential equations (BSDEs) in specific models [6, 51], extensions to more general payoff structures [38, 47, 48, 61], and so on [29, 37, 69].

Apart from the above, there are a number of other areas where the minimal entropy martingale measure has come up; these include the following:

- option price comparisons [7, 11, 32–34, 55];
- generalizations or connections to other optimal ELMMs [2, 14, 15, 66]); *see also* **Minimal Martingale Measure** and [20];
- utility maximization with a random time horizon [12];
- good deal bounds [44]; *see also* **Good-deal Bounds**; and
- a calibration game [25].

There are also many papers that simply choose the MEMM as pricing measure for option pricing applications; especially in papers from the actuarial literature, this approach is often motivated by the connections between the MEMM and the Esscher transformation. Finally, we mention that the idea of looking for a martingale measure subject to a constraint on relative entropy also naturally comes up in calibration problems; *see, for instance*, [3, 16, 17] and **Model Calibration**.

Minimal Martingale Measure

Let $S = (S_t)$ be a stochastic process on a filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t), P)$ that models the discounted prices of primary traded assets in a financial market. An equivalent local martingale measure (ELMM) for S is a probability measure Q equivalent to the original (historical) measure P such that S is a local Q -martingale (see **Equivalent Martingale Measures**). If S is a nonnegative P -semimartingale, the fundamental theorem of asset pricing says that an ELMM Q for S exists if and only if S satisfies the no-arbitrage condition (NFLVR), that is, admits no free lunch with vanishing risk (see **Fundamental Theorem of Asset Pricing**). By Girsanov's theorem, S is then under P a semimartingale with a decomposition $S = S_0 + M + A$ into a local P -martingale M and an adapted process A of finite variation. If S is special under P , then A can be chosen predictable and the resulting canonical decomposition of S is unique. We say that S satisfies the structure condition (SC) if M is locally P -square-integrable and A has the form $A = \int d\langle M \rangle \lambda$ for a predictable process λ such that the increasing process $\int \lambda' d\langle M \rangle \lambda$ is finite-valued. In an Itô process model where S is given by a stochastic differential equation $dS_t = S_t((\mu_t - r_t)dt + \sigma_t dW_t)$, the latter process is given by $\int ((\mu_t - r_t)/\sigma_t)^2 dt$, the integrated squared instantaneous Sharpe ratio of S (see **Sharpe Ratio**).

Definition 1 Suppose S satisfies (SC). An ELMM $\hat{P}$ for S with P -square-integrable density $d\hat{P}/dP$ is called minimal martingale measure (MMM) (for S) if $\hat{P} = P$ on $\mathcal{F}_0$ and if every local P -martingale L that is locally P -square integrable and strongly P -orthogonal to M is also a local $\hat{P}$ -martingale. We call $\hat{P}$ orthogonality preserving if L is also strongly $\hat{P}$ -orthogonal to S .

The basic idea for the MMM first appeared in [46] in a more specific model, where it was used as an auxiliary technical tool in the context of local risk-minimization (see also **Hedging** for an overview of key ideas on hedging and **Mean-Variance Hedging** for an alternative quadratic approach). More precisely, the so-called

locally risk-minimizing strategy for a given contingent claim H was obtained there (under some specific assumptions) as the integrand from the classical Galtchouk–Kunita–Watanabe decomposition of H under $\hat{P}$. However, the introduction of $\hat{P}$ in [46] and also in [47] was still somewhat *ad hoc*. The above definition was given in [18] where the main results presented here can also be found. In particular, [18] showed that for continuous S , the Galtchouk–Kunita–Watanabe decomposition of H under the MMM $\hat{P}$ provides (under very mild integrability conditions) the so-called Föllmer–Schweizer decomposition of H under the original measure P , and this in turn immediately gives the locally risk-minimizing strategy for H . We emphasize that this is no longer true, in general, if S has jumps. The MMM subsequently found various other applications and uses and has become fairly popular, especially in models with continuous price processes.

Suppose now S satisfies (SC). For every ELMM Q for S with $dQ/dP \in L^2(P)$, the density process then takes the form

$$Z^Q := \frac{dQ}{dP} \Big|_{\mathcal{F}} = Z_0^Q \mathcal{E} \left(- \int \lambda dM + L^Q \right) \quad (1)$$

with some locally P -square-integrable local P -martingale L^Q . If the MMM $\hat{P}$ exists, then it has $\hat{Z}_0 = 1$ and $L^{\hat{P}} \equiv 0$, and its density process is thus given by the stochastic exponential (see **Stochastic Exponential**)

$$\begin{aligned} \hat{Z} &= \mathcal{E} \left(- \int \lambda dM \right) \\ &= \exp \left(- \int \lambda dM - \frac{1}{2} \int \lambda' d[M] \lambda \right) \\ &\quad \times \prod (1 - \lambda' \Delta M) \exp \left(\lambda' \Delta M + \frac{1}{2} (\lambda' \Delta M)^2 \right) \end{aligned} \quad (2)$$

The advantage of this explicit representation is that it allows to determine the MMM $\hat{P}$ and its density process $\hat{Z}$ directly from the ingredients M and λ of the canonical decomposition of S . Conversely, one can start with the above expression for $\hat{Z}$ to define a candidate for the density process of the MMM. This gives existence of the MMM under the following conditions:

1. $\hat{Z}$ is strictly positive; this happens if and only if $\lambda' \Delta M < 1$, that is, all the jumps of $\int \lambda dM$ are strictly below 1.
2. The local P -martingale $\hat{Z}$ is a true P -martingale.
3. $\hat{Z}$ is P -square-integrable.

Condition 1 automatically holds (on any finite time interval) if S , hence also M , is continuous; it typically fails in models where S has jumps. Conditions 2 and 3 can fail even if 1 holds and even if there exists some ELMM for S with P -square-integrable density; see [45] or [15] for a counterexample.

The above explicit formula for $\hat{Z}$ shows that $\hat{P}$ is minimal in the sense that its density process contains the smallest number of symbols among all ELMMs Q . More seriously, the original idea was that $\hat{P}$ should turn S into a (local) martingale while having a minimal impact on the overall martingale structure of our setting. This is captured and made precise by the definition. If S is continuous, one can show that $\hat{P}$ is even orthogonality preserving; see [18] for this, and note that this usually fails if S has jumps.

To some extent, the naming of the “minimal” martingale measure is misleading since $\hat{P}$ was not originally defined as the minimizer of a particular functional on ELMMs. However, if S is continuous, Föllmer and Schweizer [18] have proved that $\hat{P}$ minimizes

$$Q \mapsto H(Q|P) - E_Q \left[\int_0^\infty \lambda'_u d\langle M \rangle_u \lambda u \right] \quad (3)$$

over all ELMMs Q for S ; see also [49]. Moreover, Schweizer [50] has shown that if S is continuous, then $\hat{P}$ minimizes the reverse relative entropy $H(P|Q)$ over all ELMMs Q for S ; this no longer holds if S has jumps. Under more restrictive assumptions, other minimality properties for $\hat{P}$ have been obtained by several authors. However, a general result under the sole assumption (SC) is not available so far.

There is a large amount of literature related to the MMM. In fact, a Google Scholar search for “minimal martingale measure” (enclosed in quotation marks) produced in April 2008 a list of well over 400 hits. As a first category, this contains papers where the MMM is studied *per se* or used as in the original approach of local risk-minimization. In terms of topics, the following areas of related work can be found in that category:

- Properties, characterization results, and generalizations for the MMM: [1, 4, 9–11, 14, 19, 33, 36, 37, 49, 51];
- Convergence results for option prices (computed under the MMM): [25, 32, 42, 44];
- Applications to hedging: [7, 39, 47, 48] (*see also Hedging*).
- Uses for option pricing: [8, 13, 55], to name only a very few; comparison results for option prices are given in [22, 24, 34] (*see also Risk-neutral Pricing*).
- Problems and counterexamples: [15, 16, 43, 45, 52].
- Equilibrium justifications for using the MMM: [26, 40].

A second category of papers contains those where the MMM has (sometimes unexpectedly) come up in connection with various other problems and topics in mathematical finance. Examples include the following:

- Classical utility maximization and utility indifference valuation [3, 20, 21, 23, 35, 41, 53, 54]: the MMM here often appears because the special structure of a given model implies that $\hat{P}$ has a particular optimality property (*see also Expected Utility Maximization; Expected Utility Maximization: Duality Methods; Utility Indifference Valuation; and Minimal Entropy Martingale Measure*).
- The numeraire portfolio and growth-optimal investment [2, 12]: this is related to the minimization of the reverse relative entropy $H(P|\cdot)$ over ELMMs (*see also Kelly Problem*).
- The concept of value preservation [28–30]: here the link seems to come up because value preservation is, like local risk-minimization, a local optimality criterion.
- Good deal bounds in incomplete markets [5, 6]: the MMM naturally shows up here because good deal bounds are formulated *via* instantaneous quadratic restrictions on the pricing kernel (ELMM) to be chosen (*see also Good-deal Bounds; Sharpe Ratio; Market Price of Risk*).
- Local utility maximization [27]; again, the link here is due to the local nature of the criterion that is used.
- Risk-sensitive control [17, 31, 38]; this is an area where the connection to the MMM seems

not yet well understood. See also **Risk-sensitive Asset Management**.

Good-deal Bounds

Most contingent claims valuation is based, at least notionally, on the concept of exact replication. The difficulties of exactly replicating derivative positions suggest that in many cases we should, instead, put bounds around the value of an instrument. These bounds ought to depend on model assumptions and on the prices of securities that would be used to exploit mispricing. No-arbitrage bounds are often very weak, so good-deal bounds provide an attractive alternative.

Good-deal bounds provide a range of prices within which an instrument must trade if it is not to offer a surprisingly good reward-for-risk opportunity. This is illustrated in Figure 1, where the horizontal axis represents the distribution of future payoffs (or values) after zero cost hedging. In an incomplete market setting, rather strong assumptions are needed to arrive at a unique forward value, such as p^* in the figure. Conversely, risk-free arbitrage typically allows a rather wide band of prices, as between the upper and lower bounds b_+ , b_- . We can hope to obtain a much narrower band without the need for strong assumptions if we simply preclude profitable opportunities. This gives the good-deal bounds p_+ and p_- . These bounds have two alternative interpretations: we can think of them as establishing normative bid and ask forward prices for a particular trader or as predicting a range in which we expect the market price to lie.

This line of valuation analysis now has an interesting history and it has inspired a quite significant literature, much of it very mathematical. There are a great many different variations by which the philosophy just described can be implemented.

This article aims to cover the main issues without going too deeply into mathematical technicalities. We begin by considering a simple illustrative example to provide intuitive insights into the nature of the analysis, including the use of duality in the solutions. We then sketch the history of this topic, including the generalized Sharpe ratio. Finally, there is a discussion of the role of the utility function (*see Utility Function*) in the analysis, of applications, and of the more recent literature.

Illustration

Consider the problem faced by a financial intermediary in determining reservation bid and ask prices

for some derivative which can, at best, only be partly hedged. There is no chance of replicating this claim exactly, and super-replication bounds may be too loose to be practically helpful. The company expects to trade using some kind of statistical arbitrage, for which each transaction passes a minimum reward-for-risk threshold and overall to obtain a portfolio that performs much better than that minimum.

More specifically, reservation forward bid and ask prices $p_- < p_+$ are to be determined at time zero for a derivative that will pay a random amount $\tilde{C}_T$ at later date T . We suppose a von Neumann–Morgenstern utility function $U(\cdot)$ for date T wealth and a forward wealth endowment of W_0 . The reservation prices are constructed so that trade will provide a level of expected utility at a predetermined level U_R that exceeds the expected utility that could be reached without it by $A > 0$.

Figure 2 illustrates the construction. The horizontal axis represents the price of the contingent claim. The vertical axis represent the expected utility obtained from buying (or selling) the optimal quantity of the claim. Outside the super-replication bounds, b_- , b_+ , unbounded wealth can be obtained.

In the case where no hedging will be undertaken and the forward price of the claim is p , we simply have the optimization of the quantity θ bought or sold as

$$\underset{\theta}{Max} E \left[U \left(W_0 + \theta \left(\tilde{C}_T - p \right) \right) \right] \quad (1)$$

If p is low enough we will expect to buy the claim, and if p is high enough we will want to sell it. Intuitively the good-deal lower bound, p_- , is the highest price at which we can buy the claim and obtain expected utility of U_R , and the good-deal upper bound, p_+ , is the lowest price at which we can sell the claim and obtain expected utility of U_R .

Now consider the first-order conditions from the optimization:

$$E \left[\left(\tilde{C}_T - p \right) U' \left(W_0 + \theta \left(\tilde{C}_T - p \right) \right) \right] = 0, \text{ so } \quad (2)$$

$$p = \frac{E \left[\tilde{C}_T \left[U' \left(\tilde{W}_T \right) \right] \right]}{E \left[U' \left(\tilde{W}_T \right) \right]},$$

$$\text{where } \tilde{W}_T = W_0 + \theta \left(\tilde{C}_T - p \right) \quad (3)$$

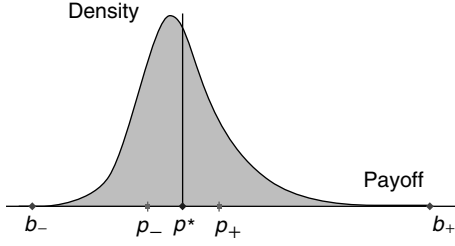

Figure 1 Good-deal bounds. Alternative forward prices and the distribution of future values after zero cost hedging: b_- , b_+ : super-replication bounds; p_- , p_+ : good-deal bounds; p^* : unique (indifference) price

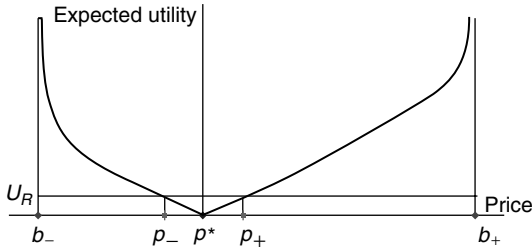

Figure 2 Expected utility against price. The good-deal bounds, p_- , p_+ , are defined as the prices at or beyond which expected utility of U_R can be obtained

Thus, the reservation price corresponds to pricing with stochastic discount factors induced by the marginal utility at the optimal wealth levels corresponding to this price.

In principle, the extension to hedging is straightforward. The gains or losses from a self-financing strategy with zero initial cost are simply added into the date T wealth. If at date t the strategy involves holdings x_t at prices P_t , the expression for wealth at date T becomes

$$\tilde{W}_T = W_0 + \theta (\tilde{C}_T - p) + \int_0^T x_t dP_t \quad (4)$$

Ideally, we would like to find and use the optimum hedging strategies, but any strategies that enhance expected utility will provide tighter reservation prices. Note that if the claim can be replicated exactly, then both the good-deal bounds will tend to the replication cost. Similarly, the good-deal bounds will always be at least as tight as any super-replication bounds that can be based on the same assumptions.

So far, we have only described the primal view of this problem. Well-known duality results provide an alternative viewpoint that provides both insights and alternative computational schemes. The good-deal lower bound is characterized as the infimum of values over nonnegative changes of measure, m , that price all reference assets and have insufficient dispersion to provide higher levels of expected utility. For example,

$$p_- = \inf_{m \geq 0} \left\{ E \left[m \tilde{C}_T \right] \right\} \text{ subject to} \\ E[V(m)] \leq A, \quad E[mS_T] = S_0 \quad (5)$$

where $V(m)$ is the conjugate function of U , defined by

$$V(m) = \sup_{S_T} \{U(S_T) - mS_T\} \text{ for } m > 0 \quad (6)$$

and the final constraint in equation (5) represents the correct pricing of reference assets.

Note that this only differs from the formulation for super-replication (no-arbitrage) bounds by the addition of the inequality constraint in equation (5), which precludes extreme changes of measure that would generate expected utility greater than U_R . In both cases, the more assets we hedge with, the more the change of measure is constrained and the tighter the valuation bounds.

Early Literature

Finding bounds on the values of derivatives has a long history. Merton [15] summarizes the conventional upper and lower bounds on vanilla options and how they are enforced by arbitrage. The subsequent contributions of Harrison and Kreps [10], Dybvig and Ross [8], and others have shown the pricing implications of no arbitrage more generally. Later papers by Perrakis and Ryan [16] and Levy [14] obtained slightly more general bounds on the prices of options, for example, based on stochastic dominance by adding some additional stronger assumptions. More recently a number of papers, such as [11], have considered super-replication bounds on exotic options when vanilla options can be used to engineer the hedge (*see Arbitrage Bounds*). Interest in this topic has further intensified with the growth of the literature on Levy processes (*see Exponential Lévy Models*), exotic options, and incomplete markets.

Much of the work in the incomplete markets literature focuses on ways to obtain a particular pricing measure and hence unique prices (for example, see **Minimal Entropy Martingale Measure**; **Minimal Martingale Measure** and Schweizer [17]), but it is not clear why a particular agent would be prepared to trade at these prices.

The good-deal literature represents an important alternative between these two paths. Hansen and Jagannathan [9] provide a crucial stepping stone. They showed that the Sharpe ratio on any security is bounded by the coefficient of variation of the stochastic discount factor (see **Stochastic Discount Factors**). The Sharpe ratio provides a very natural benchmark (see [18]) and Cochrane and Saá-Requejo [6] subsequently used this to limit the volatility of the stochastic discount factor and infer the first no-good-deal prices, conditional on the absence of high Sharpe ratios. At about the same time, a related paper by Bernardo and Ledoit [2] showed how similar bounds could be obtained relative to a maximum gain–loss ratio for the economy as a whole. These papers have their disadvantages. Cochrane and Saá-Requejo work with quadratic utility (and sometimes truncated quadratic utility), whereas Bernardo and Ledoit use Domar–Musgrave utility (i.e., two linear segments). This led Hodges [12] to investigate bounds based on the more conventional choice of exponential utility and to thereby introduce the idea of a generalized Sharpe ratio.

This concept was extended by Černý and Hodges [5] into the more general framework of good-deal pricing mostly used today. By then, it was already clear that these prices satisfied the criteria for coherent risk measures of Artzner *et al.*, [1], namely, the linearity, subadditivity, and monotonicity properties. This includes the representation of the lower good-deal price as an infimum over values from alternative pricing measures. Nevertheless, Jaschke and Küchler [13] provided an important clarification and unification of these ideas.

General Framework

The general framework of “no-good-deal” pricing (first described by Černý and Hodges [5]) places no-arbitrage and representative agent equilibrium at the two ends of a spectrum of possibilities. They define a *desirable claim* as one which provides a specific

level of von Neumann–Morgenstern expected utility and a *good-deal* as a desirable claim with zero or negative price. Within the analysis, it is assumed that any quantity of any claim may be bought or sold.

The economy contains a collection of claims with predetermined prices, so called basis assets. These claims generate the marketed subspace M and their prices define a price correspondence on this subspace. In an incomplete market, it is often convenient to suppose that the market is augmented in such a way that the resulting complete market contains no arbitrages. Instead, we can more powerfully augment the market so that the complete market contains no good-deals. We obtain a set of pricing functionals that form a subset of those that simply preclude arbitrage.

The link between no arbitrage and strictly positive pricing rules carries over to good-deals and enables price restrictions to be placed on nonmarketed claims. Under suitable technical assumptions, the no-good-deal price region for a set of claims is a convex set, and redundant assets have unique good-deal prices.

With an *acceptance set* of deals, K , typically defined in terms of expected utility, the upper and lower good-deal bounds can be defined simply as

$$p_+ = \inf_{p, x_t} \left\{ p | -\tilde{C}_T + p + \int_0^T x_t dS_t \in K \right\} \text{ and } (7)$$

$$p_+ = \inf_{p, x_t} \left\{ p | \tilde{C}_T - p + \int_0^T x_t dS_t \in K \right\} \quad (8)$$

For a given utility function, the positions of the good-deal bounds naturally depend on the required expected utility premium, A . The higher this level, the further apart the bounds will be. Coherent risk measures, well into the tails of the final distribution, can be obtained if high levels are employed for A . Except for the case of exponential utility, the bounds also depend on the initial wealth level.

Generalized Sharpe Ratios

One method for setting the required premium comes from the Sharpe ratio available on a market opportunity. This give rise to what are called generalized Sharpe ratio bounds (see [12] or [4]). The idea is to first compute the level of expected utility U_R attainable from a market opportunity offering a specific annualized Sharpe ratio, such as 0.25, and without any investment in the derivative. The good-deal

bounds that are supported by this level of expected utility (but without this market opportunity) are then said to correspond to a generalized Sharpe ratio of 0.25. In the case of negative exponential utility, the wealth level and the risk aversion parameter play the same role and become irrelevant since the opportunity can be accepted at any scale. This provides a particularly simple implementation with minimal parameter requirements.

Subsequent analysis by Černý [4] further expands both the notions and the analysis of generalized Sharpe ratios. The analysis provides details of the dual formulations for alternative standard utility functions. For example, the dual constraints on the change of measure m for different utility functions are as given in Table 1.

The various properties of the utility affect the details of the mathematical analysis considerably. For some features to work cleanly we need unbounded utility, whereas for others the behavior for low wealth levels is critical. Exponential utility precludes any delta hedge that gives a short lognormal position over finite time—even though it would have a smaller standard deviation than the fully covered position. Capping such a liability at a finite level can therefore have a big effect on the good-deal price resulting from such an analysis. Depending on the context, this may or may not be desirable. While exponential utility precludes fat negative tails, such as the short lognormal, power and log utility preclude the possibility of any negative future wealth, and even stronger effects can, in principle, derive from this.

With constant absolute risk aversion (CARA) utility, changing the scale of investment is equivalent to changing the level of risk aversion. With constant relative risk aversion (CRRA), it is equivalent to scaling the initial wealth, W_0 . The CRRA-based good-deal bound thus searches across measures with the same exponent, but different wealth levels. There may be some advantages to finding alternative utility functions that have properties intermediate between

the Domar–Musgrave function used by Bernardo and Ledoit and the negative exponential one.

Coherent Risk Measures

Jaschke and Küchler [13] expand the link between good-deal bounds and coherent risk measures. They show that there is a one-to-one correspondence between

1. “coherent risk measures” (*see* **Convex Risk Measures**)
2. cones of “desirable claims”
3. partial orderings
4. good-deal valuation bounds
5. sets of “admissible” price systems.

It should be noted from this analysis that it is sufficient but not necessary to use expected utility to define all the abstract measures considered in their paper. In other words, acceptance sets must be consistent with coherence, but not necessarily with expected utility.

It is clear from the foregoing that good-deal analysis can easily be applied as the basis of risk measurement and will satisfy the axioms of coherent risk measures (*see* **Convex Risk Measures**). They can also be applied as a method of risk adjustment for performance measurement. For example, a utility-based generalized Sharpe ratio, when applied to an empirical distribution, provides a method of adjusting for skewness in the distribution. In doing so, it makes sense to apply a negative sign to situations where a short position would have been optimal.

Recent and Prospective Literature

Important new papers continue to appear quite regularly; a few recent ones are mentioned here. Staum [19] provides much of the background, treating good-deals from the perspective of convex optimization. Bjork and Slinko [3] provide extensions to Cochrane and Saá-Requejo in a multidimensional jump-diffusion setting. There are further papers that expand on the dynamic aspects of this analysis, apply it to settings with stochastic volatility, or implement similar optimizations using mathematical programming. There are also a number of papers, which although not directly within the framework developed here, deal with related ideas in different ways.

Table 1 Stochastic discount factor constraints for various utility functions

Utility function	Constraint
Quadratic: Cochrane <i>et al.</i>	$E[m^2] \leq 1 + A^2$
Exponential	$E[m \ln m] \leq A$
Power, RRA = γ	$E[m^{1-1/\gamma}] \leq (1 + \frac{A}{\gamma})^{1/\gamma-1}$
Logarithmic	$-E[\ln m] \leq \ln(1 + A)$

The apparently simple concept of good-deal bounds has turned out to provide a great deal of richness for mathematicians to analyze, and there are now many variations on this theme in the published literature. Although the theory stems from a practical desire, very few of the papers have an applied flavor. Rather little algorithmic or numerical work has been reported, and most of that uses only somewhat simplified models, seldom calibrated to the market. The good-deal bounds approach could easily be adapted to deal with model risk, something which is hinted at in Cont [7]. The literature needs more real applications, and, perhaps, the balance will have changed when the next survey of this area comes to be written.

Arrow–Debreu Prices

Arrow–Debreu prices are the prices of “atomic” time and state-contingent claims, which deliver one unit of a specific consumption good if a specific uncertain state realizes at a specific future date. For instance, claims on the good “ice cream tomorrow” are split into different commodities depending on whether the weather will be good or bad, so that good-weather and bad-weather ice cream tomorrow can be traded separately. Such claims were introduced by Arrow and Debreu in their work on general equilibrium theory under uncertainty, to allow agents to exchange state and time contingent claims on goods. Thereby the general equilibrium problem with uncertainty can be reduced to a conventional one without uncertainty. In finite-state financial models, Arrow–Debreu securities delivering one unit of the numeraire good can be viewed as natural atomic building blocks for all other state–time contingent financial claims; their prices determine a unique arbitrage-free price system.

Arrow–Debreu Equilibrium Prices

This section explains Arrow–Debreu prices in an equilibrium context, where they originated, see [1, 3]. We first consider a single-period model with uncertain states that will be extended to multiple periods later. For this exposition, we restrict ourselves to a single consumption good only, and consider a pure exchange economy without production.

Let $(\Omega, \mathcal{F})$ be a measurable space of finitely many outcomes $\omega \in \Omega = \{1, 2, \dots, m\}$, where the σ -field $\mathcal{F} = 2^\Omega$ is the power set of all events $A \subset \Omega$. There is a finite set of agents, each seeking to maximize the utility $u^a(c^a)$ from his or her consumption $c^a = (c_0^a, c_1^a(\omega)_{\omega \in \Omega})$ at present and future dates 0 and 1, given some endowment that is denoted by a vector $(e_0^a, e_1^a(\omega)) \in \mathbb{R}_{++}^{1+m}$. For simplicity, let consumption preferences of agent a be of the expected utility form

$$u^a(c^a) = U_0^a(c_0) + \sum_{\omega=1}^m P^a(\omega) U_\omega^a(c_1(\omega)) \quad (1)$$

where $P^a(\omega) > 0$ are subjective probability weights, and the direct utility functions U_ω^a and U_0^a are, for present purposes, taken to be of the form $U_i^a(c) =$

$d_i^a c^\gamma / \gamma$ with relative risk aversion coefficient $\gamma = \gamma^a \in (0, 1)$ and discount factors $d_i^a > 0$. This example for preferences satisfies the general requirements (insaturation, continuity and convexity) on preferences for state-contingent consumption in [3], which need not be of the separable subjective expected utility form above. The only way for agents to allocate their consumption is by exchanging state-contingent claims for the delivery of some units of the (perishable) consumption good at a specific future state. Let q_ω denote the price at time 0 for the state-contingent claim that pays $q_0 > 0$ units if and only if state $\omega \in \Omega$ is realized. Given the endowments and utility preferences of the agents, an equilibrium is given by consumption allocations c^{a*} and a linear price system $(q_\omega)_{\omega \in \Omega} \in \mathbb{R}_+^m$ such that,

1. for any agent a , his or her consumption c^{a*} maximizes $u^a(c^a)$ over all c^a subject to budget constraint $(c_0^a - e_0^a)q_0 + \sum_\omega (c_1^a - e_1^a)(\omega)q_\omega \leq 0$, and
2. markets clear, that is $\sum_a (c_t^a - e_t^a)(\omega) = 0$ for all dates $t = 0, 1$ and states ω .

An equilibrium exists and yields a *Pareto optimal* allocation; see [3], Chapter 7, or the references below. Relative equilibrium prices q_ω/q_0 of the Arrow securities are determined by first-order conditions from the ratio of marginal utilities evaluated at optimal consumption: for any a ,

$$\frac{q_\omega}{q_0} = P^a(\omega) \frac{\partial}{\partial c_1^a} U_\omega^a(c_1^{a*}(\omega)) \Big/ \frac{\partial}{\partial c_0^a} U_0^a(c_0^{a*}) \quad (2)$$

To demonstrate the existence of equilibrium, the classical approach is to show that excess demand vanishes, that is markets clear, by using a fixed point argument (see Chapter 17 in [8]). To this end, it is convenient to consider c^a , e^a and $q = (q_0, q_1, \dots, q_m)$ as vectors in $\mathbb{R}^{1+m}$. Since only relative prices matter, we may and shall suppose that prices are normalized so that $\sum_0^m q_i = 1$, that is, the vector q lies in the unit simplex $\Delta = \{q \in \mathbb{R}_+^{1+m} \mid \sum_0^m q_i = 1\}$. The budget condition 1 then reads compactly as $(c^a - e^a)q \leq 0$, where the left-hand side is the inner product in $\mathbb{R}^{1+m}$. For given prices q , the optimal consumption of agent a is given by the inverse of the marginal utility, evaluated at a multiple of the state price density (see equation (12) for the general definition in the multiperiod case), as

$$c_0^{a*} = c_0^{a*}(q) = (U_0^{a'})^{-1}(\lambda^a q_0) \text{ and}$$

$$c_{1,\omega}^{a*} = c_{1,\omega}^{a*}(q) = (U_\omega^{a'})^{-1}(\lambda^a q_\omega / P^a(\omega)), \quad \omega \in \Omega \quad (3)$$

where $\lambda^a = \lambda^a(q) > 0$ is determined by the budget constraint $(c^{a*} - e^a)q = 0$ as the Lagrange multiplier associated to the constrained optimization problem 1. Equilibrium is attained at prices q^* where the aggregate excess demand

$$z(q) := \sum_a (c^{a*}(q) - e^a) \quad (4)$$

vanishes, that is $z(q^*) = 0$. One can check that $z : \Delta \rightarrow \mathbb{R}^{1+m}$ is continuous in the (relative) interior $\Delta^{\text{int}} := \Delta \cap \mathbb{R}_{++}^{1+m}$ of the simplex, and that $|z(q^n)|$ goes to ∞ when q^n tends to a point on the boundary of Δ . Since each agent exhausts his or her budget constraint 1. with equality, Walras' law $z(q)q = 0$ holds for any $q \in \Delta^{\text{int}}$. Let Δ^n be an increasing sequence of compact sets exhausting the simplex interior: $\Delta^{\text{int}} = \bigcup_n \Delta^n$. Set $v^n(z) := \{q \in \Delta^n \mid zq \geq zp \ \forall p \in \Delta^n\}$, and consider the correspondence (a multivalued mapping)

$$\Pi^n : (q, z) \mapsto (v^n(z), z(q)) \quad (5)$$

that can be shown to be convex, nonempty valued, and maps the compact convex set $\Delta^n \times z(\Delta^n)$ into itself. Hence, by Kakutani's fixed point theorem, it has a fixed point $(q^{n*}, z^{n*}) \in \Pi^n(q^{n*}, z^{n*})$. This implies that

$$z(q^{n*})q \leq z(q^{n*})q^{n*} = 0 \quad \text{for all } q \in \Delta^n \quad (6)$$

using Walras' law. A subsequence of q^{n*} converges to a limit $q^* \in \Delta$. Provided one can show that q^* is in the interior simplex Δ^{int} , existence of equilibrium follows. Indeed, it follows that $z(q^*)q \leq 0$ for all $q \in \Delta^{\text{int}}$, implying that $z(q^*) = 0$ since $z(q^*)q^* = 0$ by Walras' law. To show that any limit point of q^{n*} is indeed in Δ^{int} , it suffices to show that $|z(q^{n*})|$ is bounded in n , recalling that z explodes at the simplex boundary. Indeed, $z = \sum_a z^a$ is bounded from below since each agent's excess demand satisfies $z^a = c^a - e^a \geq -e^a$. This lower bound implies also an upper bound, by using equation (6) applied with some $q \in \Delta^1 \subset \Delta^n$, since $0 < \epsilon \leq q_i \leq 1$ uniformly in i . This establishes existence of equilibrium. To ensure uniqueness of equilibrium, a sufficient condition is that all agents' risk aversions are less than or equal to 1, that is $\gamma^a \in (0, 1]$ for all a , see [2].

For multiple consumption goods, the above ideas generalize if one considers consumption bundles and state-contingent claims of every good. Arrow [1] showed that in the case of multiple consumption goods, all possible consumption allocations are spanned if agents could trade as securities solely state-contingent claims on the unit of account (so-called *Arrow securities*), provided that spot markets with anticipated prices for all other goods exists in all future states. In the sequel, we only deal with Arrow securities in financial models with a single numeraire good that serves as unit of account, and could for simplicity be considered as money ("euro"). If the set of outcomes Ω were (uncountably) infinite, the natural notion of atomic securities is lost, although a state price density (stochastic discount factor, deflator) may still exist, which could be interpreted intuitively as an Arrow–Debreu state price per unit probability.

Multiple Period Extension and No-arbitrage Implications

The one-period setting with finitely many states is easily extended to finitely many periods with dates $t \in \{0, \dots, T\}$ by considering an enlarged state space of suitable date–event pairs (see Chapter 7 in [3]). To this end, it is mathematically convenient to describe the information flow by a filtration $(\mathcal{F}_t)$ that is generated by a stochastic process $X = (X_t(\omega))_{0 \leq t \leq T}$ (abstract, at this stage) on the finite probability space $(\Omega, \mathcal{F}, P_0)$. Let $\mathcal{F}_0$ be trivial, $\mathcal{F}_T = \mathcal{F} = 2^\Omega$, and assume $P_0(\{\omega\}) > 0$, $\omega \in \Omega$. The σ -field $\mathcal{F}_t$ contains all events that are based on information from observing paths of X up to time t , and is defined by a partition of Ω . The smallest nonempty events in $\mathcal{F}_t$ are “ t -atomic” events $A \in \mathcal{A}_t$ of the type $A = [x_0 \cdots x_t] := \{X_0 = x_0, \dots, X_t = x_t\}$, and constitute a partition of Ω . Figure 1 illustrates the partitions $\mathcal{A}_t$ corresponding to the filtration $(\mathcal{F}_t)_{t=0,1,2}$ in a five-element space Ω , as generated by a process X_t taking values $a, \dots, f$. It shows that a filtration can be represented by a nonrecombining tree. There are eight (atomic) date–event pairs (t, A) , $A \in \mathcal{A}_t$. An adapted process $(c_t)_{t \geq 0}$, describing, for instance, a consumption allocation, has the property that c_t is constant on each atom A of partition $\mathcal{A}_t$, and hence is determined by specifying its value $c_t(A)$ at each node point $A \in \mathcal{A}_t$ of the tree. Arrow–Debreu prices

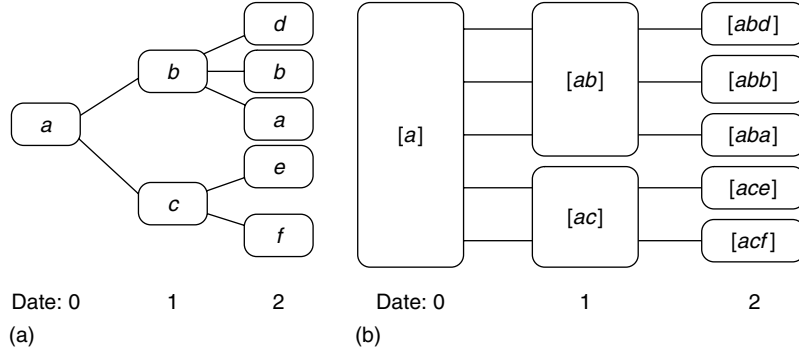

Figure 1 Equivalent representations of the multiperiod case. (a) Tree of the filtration generating process X_t . (b) Partitions $\mathcal{A}_t$ of filtration $(\mathcal{F}_t)_{t=0,1,2}$

$q(t, A)$ are specified for each node of the tree and represent the value at time 0 of one unit of account at date t in node $A \in \mathcal{A}_t$.

Technically, this is easily embedded in the previous single-period setting by passing to an extended space $\Omega' := \{1, \dots, T\} \times \Omega$ with σ -field $\mathcal{F}'$ generated by all sets $\{t\} \times A$ with A being an (atomic) event of $\mathcal{F}_t$, and $P'_0(\{t\} \times A) := \mu(t)P_0(A)$ for a (strictly positive) probability measure μ on $\{1, \dots, T\}$.

For the common no-arbitrage pricing approach in finance, the focus is to price contingent claims solely in relation to prices of other claims, that are taken as exogenously given. In doing so, the aim of the model shifts from the fundamental economic equilibrium task to explain all prices, toward a “financial engineering” task to determine prices from already given other prices solely by no-arbitrage conditions, which are a necessary prerequisite for equilibrium. From this point of view, the (atomic) Arrow–Debreu securities span a *complete market*, as every contingent payoff c , paying $c_t(A)$ at time t in atomic event $A \in \mathcal{A}_t$, can be decomposed by $c = \sum_{t, A \in \mathcal{A}_t} c_t(A)1_{(t, A)}$ into a portfolio of atomic Arrow securities, paying one euro at date t in event A . Hence the no-arbitrage price of the claim must be $\sum_{t, A \in \mathcal{A}_t} c_t(A)q(t, A)$. Given that all atomic Arrow–Debreu securities are traded at initial time 0, the market is statically complete in that any state-contingent cash flow c can be *replicated* by a portfolio of Arrow–Debreu securities that is formed *statically* at initial time, without the need for any dynamic trading. The no-arbitrage price for c simply equals the cost of replication by Arrow–Debreu securities. It is easy to check that, if all prices are determined

like this and trading takes place only at time 0, the market is free of arbitrage, given all Arrow–Debreu prices are strictly positive. To give some examples, the price at time 0 of a zero coupon bond paying one euro at date t equals $ZCB^t = \sum_{A \in \mathcal{A}_t} q(t, A)$. For the absence of arbitrage, the *t-forward prices* $q^f(t, A')$, $A' \in \mathcal{A}_t$, must be related to *spot prices* of Arrow–Debreu securities by

$$\begin{aligned} q^f(t, A') &= \frac{q(t, A')}{\sum_{A \in \mathcal{A}_t} q(t, A)} \\ &= \frac{1}{ZCB^t} q(t, A'), \quad A' \in \mathcal{A}_t \end{aligned} \quad (7)$$

Hence, the forward prices $q^f(t, A')$ are normalized Arrow–Debreu prices and constitute a probability measure Q^t on $\mathcal{F}_t$, which is the *t-forward measure* associated to the t – ZCB as numeraire, and yields $q^f(t, A) = E^t[1_A]$ for $A \in \mathcal{A}_t$, with E^t denoting expectation under Q^t . Below, we also consider “non-atomic” state-contingent claims with payoffs $c_k(\omega) = 1_{(t, B)}(k, \omega)$, $k \leq T$, for $B \in \mathcal{F}_t$, whose Arrow–Debreu prices are denoted by $q(t, B) = \sum_{A \in \mathcal{A}_t, A \subset B} q(t, A)$.

Arrow–Debreu Prices in Dynamic Arbitrage-free Markets

In the above setting, information is revealed dynamically over time, but trading decisions are static in that they are entirely made at initial time 0. To discuss relations between initial and intertemporal

Arrow–Debreu prices in arbitrage-free models with dynamic trading, this section extends the above setting, assuming that all Arrow–Debreu securities are tradable dynamically over time.

Let $q_s(t, A_t)$, $s \leq t$, denote the price process of the Arrow–Debreu security paying one euro at t in state $A_t \in \mathcal{A}_t$. At maturity t , $q_t(t, A_t) = 1_{A_t}$ takes value 1 on A_t and is 0 otherwise. For the absence of arbitrage, it is clearly necessary that Arrow–Debreu prices are nonnegative, and that $q_s(t, A_t)(A_s) > 0$ holds for $s < t$ at $A_s \in \mathcal{A}_s$ if and only if $A_s \supset A_t$. Further, for $s < t$ it must hold that

$$q_s(t, A_t)(A_s) = q_s(s+1, A_{s+1})(A_s) \times q_{s+1}(t, A_t)(A_{s+1}) \quad (8)$$

for $A_s \in \mathcal{A}_s$, $A_{s+1} \in \mathcal{A}_{s+1}$ such that $A_s \supset A_{s+1} \supset A_t$. In fact, the above conditions are also sufficient to ensure that the market model is free of arbitrage: At any date t , the Arrow–Debreu prices for the next date define the interest rate R_{t+1} for the next period $(t, t+1)$ of length $\Delta t > 0$ of a savings account $B_t = \exp(\sum_{s=1}^t R_s \Delta t)$ by

$$\begin{aligned} & \exp(-R_{t+1}(A_t)\Delta t) \\ &= \sum_{A_{t+1} \in \mathcal{A}_{t+1}(A_t), A_{t+1} \subset A_t} q_t(t+1, A_{t+1}), \\ & \text{for } A_t \in \mathcal{A}_t \end{aligned} \quad (9)$$

which is locally riskless, in that R_{t+1} is known at time t , that means it is $\mathcal{F}_t$ -measurable. They define an equivalent *risk neutral probability* Q^B by determining its transition probabilities from any $A_t \in \mathcal{A}_t$ to $A_{t+1} \in \mathcal{A}_{t+1}$ with $A_t \supset A_{t+1}$ as

$$Q^B(A_{t+1}|A_t) = \frac{q_t(t+1, A_{t+1})(A_t)}{\sum_{A \in \mathcal{A}_{t+1}, A \subset A_t} q_t(t+1, A)(A_t)} \quad (10)$$

The transition probability (10) can be interpreted as one-period forward price when being at A_t at time t , for one euro at date $t+1$ in event A_{t+1} , cf. (7). Since all B -discounted Arrow–Debreu price processes $q_s(t, A_t)/B_s$, $s \leq t$, are martingales under Q^B thanks to equations (8, 10), the model is free of arbitrage by the fundamental theorem of asset pricing, see [6]. For initial Arrow–Debreu prices, denoted

by $q_0(t, A_t) \equiv q(t, A_t)$, the martingale property and equations (8, 10) imply that

$$q(t+1, A_{t+1}) = e^{-R_{t+1}(A_t)\Delta t} Q^B(A_{t+1}|A_t)q(t, A_t) \quad (11)$$

Hence $q(t, A_t) = Q^B(A_t)/B_t(A_t)$ for $A_t \in \mathcal{A}_t$.

The *deflator* or *state price density* for agent a is the adapted process ζ_t^a defined by

$$\zeta_t^a(A_t) := \frac{q(t, A_t)}{P^a(A_t)} = \frac{Q^B(A_t)}{B_t(A_t)P^a(A_t)}, \quad A_t \in \mathcal{A}_t \quad (12)$$

so that $\zeta_t^a S_t$ is a P^a -martingale for any security price process S , e.g. $S_t = q_t(T, A_T)$, $t \leq T$, with $A_T \in \mathcal{A}_T$. If one chooses, instead of B_t , another security $N_t = \sum_{A_T \in \mathcal{A}_T} N_T(A_T)q_t(T, A_T)$ with $N_T > 0$ as the numeraire asset for discounting, one can define an equivalent measure Q^N by

$$\frac{Q^N(A)}{P^a(A)} = \frac{N_T(A)}{N_0(A)} \zeta_T^a(A), \quad A \in \mathcal{A}_T \quad (13)$$

which has the property that S_t/N_t is a Q^N -martingale for any security price process S . Taking $N = (ZCB_t^T)_{t \leq T}$ as the T -zero-coupon bond yields the T -forward measure Q^T .

If X is a Q^B -Markov process, the conditional probability $Q^B(A_{t+1}|A_t)$ in equation (11) is a transition probability $p_t(x_{t+1}|x_t) := Q^B(X_{t+1} = x_{t+1}|X_t = x_t)$, where $A_k = [x_1 \dots x_k]$ for $k = t, t+1$. By summation of suitable atomic events

$$\begin{aligned} & q(t+1, X_{t+1} = x_{t+1}) \\ &= \sum_{x_t} e^{-R(x_t)\Delta t} p_t(x_{t+1}|x_t)q(t, X_t = x_t) \end{aligned} \quad (14)$$

where the sum is over all x_t from the range of X_t .

Application Examples: Calibration of Pricing Models

The role of Arrow–Debreu securities as “atomic building blocks” is theoretical, in that there exist no corresponding securities in real financial markets. Nonetheless, they are of practical use in the calibration of pricing models. For this section, X is taken to be a Q^B -Markov process, possibly time-inhomogeneous.

The first example concerns the calibration of a short rate model to some given term structure of zero coupon prices $(ZCB_t)_{t \leq T}$, implied by market quotes. For such models, a common calibration procedure relies on a suitable time-dependent shift of the state space for the short rate (see [7], Chapter 28.7). Let suitable functions R_t^* be given such that the variations of $R_t^*(X_t)$ already reflect the desired volatility and mean-reversion behavior of the (discretized) short rate. Making an ansatz $R_t(X_t) := R_t^*(X_t) + \alpha_t$ for the short rate, the calibration task is to determine the parameters α_t , $1 \leq t \leq T$, such that

$$ZCB_t = E^B \left[\exp \left(- \sum_{k \leq t} (R_k^*(X_k) + \alpha_k) \Delta t \right) \right] \quad (15)$$

with the expectation being taken under the risk neutral measure Q^B . It is obvious that this determines all the α_t uniquely. When computing this expectation to obtain the α_t by forward induction, it is efficient to use Arrow–Debreu prices $q(t, X_t = x_t)$, since X usually can be implemented by a recombining tree. Summing over the range of states x_t of X_t is more efficient than summing over all paths of X . Suppose that α_k , $k \leq t$, and $q(t, X_t = x_t)$ for all values x_t have been computed already. Using equation (14), one can then compute α_{t+1} from equation

$$ZCB_{t+1} = \sum_{x_{t+1}} \sum_{x_t} q(t, X_t = x_t) \times e^{(R_{t+1}^*(x_t) + \alpha_{t+1}) \Delta t} p_t(x_{t+1} | x_t) \quad (16)$$

where the number of summand in the double sum is typically bounded or grows at most linearly in t . Then Arrow–Debreu prices $q(t+1, X_{t+1} = x_{t+1})$ for the next date $t+1$ are computed using equation (14), while those for t can be discarded.

The second example concerns the calibration to an implied volatility surface. Let X denote the discounted stock price $X_t = S_t \exp(-rt)$ in a trinomial tree model with constant interest $R_t := r$ and $\Delta t = 1$. Each X_{t+1}/X_t can attain three possible values $\{m, u, d\} := \{1, e^{\pm \sigma \sqrt{2}}\}$ with positive probability, for $\sigma > 0$. The example is motivated by the task to calibrate the model to given prices of European calls and puts by a suitable choice of the (nonunique) risk neutral Markov transition probabilities for X_t . We focus here on the main step for this task, which is to show that the Arrow–Debreu

prices of all state-contingent claims, which pay one unit at some t if $X_t = x_t$ for some x_t , already determine the risk neutral transition probabilities of X . It is easy to see that these prices are determined by those of calls and puts for sufficiently many strikes and maturities. Indeed, strikes at all tree levels of the stock for each maturity date t are sufficient, since Arrow–Debreu payoffs are equal to those of suitable butterfly options that are combinations of such calls and puts. From given Arrow–Debreu prices $q(t, X_t = x_t)$ for all t, x_t , the transition probabilities $p_t(x_{t+1} | x_t)$ are computed as follows: starting from the highest stock level x_t at some date t , one obtains $p_t(x_t u | x_t)$ by equation (14) with $R_t(x_t) = r$ and $\Delta t = 1$. The remaining transition probabilities $p_t(x_t m | x_t)$, $p_t(x_t d | x_t)$ from (t, x_t) are determined from

$$p_t(x_t u | x_t)u + p_t(x_t m | x_t)m + p_t(x_t d | x_t)d = 1 \quad (17)$$

and $p_t(x_t u | x_t) + p_t(x_t m | x_t) + p_t(x_t d | x_t) = 1$. Using these results, the transition probabilities from the second highest (and subsequent) stock level(s) are implied by equation (14) in a similar way. This yields all transition probabilities for any t .

To apply this in practice, the call and put prices for the maturities and strikes required would be obtained from real market quotes, using suitable interpolation, and the trinomial state space (i.e., $\sigma, r, \Delta t$) has to be chosen appropriately to ensure positivity of all p_t , see [4, 5].

Options: Basic Definitions

A financial *option* is a contract conferring on the holder the right, but not the obligation, to engage in some transaction, on precisely specified terms, at some time in the future. When the holder does decide to engage in the transaction, he/she is said to *exercise the option*. There are two parties to an option contract, generally known as the *writer* and the *buyer* or *holder*. The “optionality” accrues to the buyer; the writer has the obligation to carry out his/her side of the transaction, should the buyer exercise the option. An option is *vulnerable* if there is considered to be nonnegligible risk that the writer will fail to do this, that is, he/she will default on his/her side of the contract.

The classic contracts are European call and put options. A **call option** entitles the holder to purchase a specified number N of units of a security at a fixed price K per unit, at a specified time T . If S_T is the market price of the security at time T , the holder will exercise the option if and only if $S_T > K$ (otherwise, it would be cheaper to buy in the market). Since the holder has now acquired for K per unit something that is worth S_T , he/she makes a profit of $N(S_T - K)$. Thus, in general, the profit is $N[S_T - K]^+ = N \max(S_T - K, 0)$. Similarly, the profit on a contract, entitling the holder to *sell* at K , is $N[K - S_T]^+$. The asset on which the option is written is called the *underlying asset*. A call option is *in the money* if $S_T > K$, *at the money* (ATM) if $S_T = K$ and *out of the money* if $S_T < K$. These terms are also used at earlier times $t < T$ (e.g., ATM if $S_t = K$ etc.) even though the option cannot be exercised then. An option is *ATM forward* at time t if $K = F(t, T)$ where $F(t, T)$ is the **forward price** at time t for purchase at time T .

Option Contracts

In general, several assets may underlie a given contract, as for example in an **exchange option** where the holder has the right to exchange one asset for another. Options are sometimes called *contingent claims* or *derivative securities*. These two synonymous terms include options, but refer more generally to any contract whose value is a function of the values of some collection of underlying assets.

There are several binary classifications that help define an option contract.

European/American

An option is European if it must be exercised, if at all, on a specified date, or a specified sequence of dates (for example, a *cap* is an **interest-rate option** consisting of a sequence of call options on the Libor rate; each of these options is exercised when they fall due if in the money). In an **American option**, by contrast, the time of exercise is at the holder's discretion. The classic American option involves a fixed final time T and allows the holder to exercise at any time $T' \leq T$, leaving the holder with the problem of determining an exercise strategy that will maximize the value to him. This immediately implies three things: (i) the value of an American option that has not already been exercised at any time t can never be less than the *intrinsic value* ($[K - S_t]^+$ for a put option), since one possible strategy is always to exercise *now*, (ii) the value can never be less than the value of the corresponding European option, since another possible strategy is never to exercise before T , and (iii) the value is a nondecreasing function of the final maturity time, since for $T_1 < T_2$ the T_1 option is just the T_2 option with the additional restriction that it never be exercised beyond T_1 . The difference between the American and European values for the same contract is called the *early exercise premium*. Sometimes, American options have some restriction on the set of allowable exercise times; for example, the conversion option in **convertible bonds** often prohibits the investor from converting before a certain minimum time. Of course, any such restrictions reduce the value since they reduce the class of exercise strategies. A particular case is the *Bermuda option*, which can only be exercised at one of a finite number of times. This is the normal situation in interest-rate options, where there is a natural sequence of *coupon dates* at which exercise decisions may be taken. Bermuda options are presumably so called because Bermuda is somewhere between America and Europe—but much closer to America.

Traded/OTC

Traded options are those where the parties trade through the medium of an organized exchange,

while “over the counter” (OTC) options are bilateral agreements between market counterparties. Option exchanges have become increasingly globalized in recent years. They include the US–European consortium NYSE Euronext, Chicago Mercantile Exchange (CME), Eurex and EDX, all of which offer a range of financial contracts, and a number of specialist commodity exchanges such as NYMEX (oil), ICE, and the London Metal Exchange (LME). An exchange offers contracts on an underlying asset such as an individual stock or a stock index such as the S&P500, with a range of maturity times and strike values. New options are added as the old ones roll off, and the strikes offered are in a range around the spot price of the underlying asset at the time the contract is initiated (the options may turn out to be far in or out of the money at later times, of course). In a traded options market, prices are determined by supply and demand. If the exercise times are T_i and the strike values K_j then the matrix $V = [\hat{\sigma}_{ij}]$, where $\hat{\sigma}_{ij}$ is the **implied volatility** corresponding to the (T_i, K_j) contract, defines the so-called **volatility surface** that plays a key role in option risk management.

All interest-rate options and most FX (foreign exchange) options are OTC, but many are, nevertheless, very liquidly traded and market information on implied volatilities is readily available.

Physical Settlement/Cash Settlement

Many single-stock options, and **commodity options** are *physically settled*, that is, at exercise the holder pays the strike value and takes delivery of a share certificate or a barrel of oil. (One can, however, avoid physical delivery by selling the option shortly before final maturity.) The alternative is *cash settlement*, where the holder is simply paid a cash amount, such as $[S_T - K]^+$ for a call option, at exercise. When the underlying is an index like the S&P500 this is the only way—one cannot deliver the index! In this case, the amount paid is $c \times [I_T - K]^+$ where I_T is the value of the index and c is the contractually specified dollar value of one index point.

Liquid/Illiquid

Like any other traded asset, an option contract is **liquid** if there is large market depth, that is, there are a significant number of active traders in the market,

none of whom controls a significant proportion of the total supply. In these circumstances, the price is well established, since the last trade was never very long ago; bid/ask spreads will be tight, buyers and sellers can enter the market at will, and there is little room for price manipulation. By contrast, in an illiquid market, it may be hard to establish a market price when actual trades are infrequent and bid/ask spreads are wide. The liquid/illiquid classification is not immutable: a liquid market can suddenly become illiquid if there is some shock that forces everybody onto the same side of the market. Several well-recorded disasters in the derivatives market have been due to this phenomenon.

(Plain) Vanilla/Exotic

The simplest, most standard, and most widely traded options are often referred to as *plain vanilla* options. This would certainly include all exchange-traded options. An “exotic” option is an OTC option with nonstandard features of some kind, which requires significant modeling effort to value, and where different analysts could well come up with significantly different valuations. Exotic options often involve several underlying assets and complicated payment streams, but even a simple call option can be exotic if it poses significant hedging difficulties, as for example do long-dated equity options. On the other hand, barrier options, for example, which once would have been considered exotic, have now become vanilla in some markets such as FX, because they are so widely traded.

Path-dependent/Path-independent

An option is path-dependent if its exercise value depends on the value of the underlying asset at more than one time. Examples are barrier and Asian options, and any American option. The exercise value of a path-independent option is a function only of the underlying price, say S_T , at the maturity time T , as for example in **Black–Scholes**. Valuation then only requires specifying the one-dimensional risk-neutral distribution of S_T , whereas for a path-dependent option a distribution in path space is required, making the valuation more computationally intensive and model dependent.

Option Definitions

The purpose of this section is to collect together introductory definitions of various option contracts, or features of option contracts, found in the market. We refer to specialist articles in this encyclopaedia for a detailed treatment, and to standard textbooks such as Hull [1]. In these definitions, we use S_t to denote a generic underlying asset price, on which is written an option that starts at time 0 with final maturity at time T .

Asian

An **Asian option** is one whose exercise value depends on the *average price* over some range of times. Generally, this is an arithmetic average of the form $\bar{S} = (1/n) \sum_{i=1}^n S_{t_i}$ and, of course, in reality, it is always a finite sum, although for purposes of analysis it is often convenient to consider continuous averaging $\bar{S}^c = (1/T) \int_0^T S_t dt$. Averaging may be over the entire length of the contract or some much shorter period. For example, in **commodity options** call option values are generally based on the 10-day or one-month average price immediately prior to maturity, rather than on the spot price, to deter market manipulation.

Barrier

A **barrier option** involves one or both of two prices, a lower barrier $L < S_0$ and an upper barrier $U > S_0$, a strike K , and a maturity time T . Let $\tau_L = \inf\{t : S_t \leq L\}$, $\tau_U = \inf\{t : S_t \geq U\}$ and $\tau_{LU} = \min(\tau_L, \tau_U)$. A *knockout* option expires worthless if a specified one of these times occurs before T , while a *knock-in* option expires worthless *unless* this time occurs before T . An *up-and-out* call is a knockout call option based on τ_U , so formally its exercise value is $\mathbf{1}_{(\tau_U > T)}[S_T - K]^+$. Similarly, an up-and-in call has exercise value $\mathbf{1}_{(\tau_U \leq T)}[S_T - K]^+$. The sum is an ordinary call option. There are analogous definitions for down-and-out and down-and-in options based on τ_L . Normally, these would be put options. A double barrier option knocks out or in at time τ_{LU} . In the Black–Scholes model, there is an analytic formula for single-barrier options, based on the reflection principle for Brownian motion, but double barrier options require numerical methods.

Knockout options are cheaper than their plain vanilla counterparts because the exercise value is strictly less with positive probability. Essentially, the buyer of a vanilla option pays a premium for events he/she may regard as overwhelmingly unlikely. By buying a barrier option instead, he/she avoids paying this premium.

Basket

Consider a portfolio containing w_i units of asset i for $i = 1, \dots, n$. A **basket** call option then has exercise value $[X - K]^+$ where $X = \sum_i w_i S_i(T)$ is the portfolio value at time T . The main problem in valuing basket options is the enormous number of correlation coefficients involved, for even moderate portfolio size n .

Bermuda

These were already mentioned above. Probably the most common example is the **Bermuda swaption**, entitling the holder to enter a swap at an agreed fixed-side rate at any one of a list of coupon dates (or, equivalently, the right to walk away from an existing swap contract).

Chooser

A chooser option involves three times 0, T_1 , T_2 , and a strike K . The option is entered and the strike set at time 0, and at time T_1 , the holder selects whether it is to be a put or a call. The appropriate exercise value is then evaluated and paid at T_2 . Thus the value at T_1 is the maximum of the put and call values at that time. Given this fact valuation is straightforward in the Black–Scholes model.

Digital

A digital option pays a fixed cash amount if some condition is realized. For example, an up-and-in digital barrier option with maturity T and barrier level U will pay a fixed amount X if $\tau_U < T$. Payment might be made at τ_U or at T .

Exchange

An **exchange option** has exercise value $[aS_2(T) - S_1(T)]^+$, that is, the holder has the right to exchange

one unit of asset 1 for a units of asset 2 at the maturity time T . Exchange options can be priced by the Margrabe formula, originally introduced in [2].

Forward-starts, Ratchets, and Cliquets

A involves two times $0 < T_1 < T_2$. The premium is paid at time 0 and the exercise value at final maturity T_2 is $[S_{T_2} - mS_{T_1}]^+$, where m is a contractually specified “moneyness” factor. If, for example, $m = 1.05$, then effectively the strike is set at T_1 in such a way that the option is 5% out of the money at that time. This is a pure volatility play in that the value essentially only depends on the forward volatility between T_1 and T_2 . A ratchet or **cliquet** is a string of forward start options over times T_i, T_{i+1} , so T_{i+1} is the maturity date for option i and the start date for option $i + 1$.

Lookback

Let $S_{\max}(t) = \max_{u \leq t} S(u)$ and $S_{\min}(t) = \min_{u \leq t} S(u)$. The exercise values of a **lookback** call and a lookback put are $[S(T) - S_{\min}(T)]$ and $[S_{\max}(T) - S(T)]$, respectively. The holders of these options can essentially buy at the minimum price and sell at the maximum price. Black–Scholes valuation of these options uses the reflection principle for Brownian motion, in the same way as for barrier options.

Passport

A passport option is a call option where the underlying asset is a traded portfolio, and the holder has the right to choose the trading strategy in this portfolio.

Quanto

A **quanto** or *cross-currency* option is written on an underlying asset denominated in currency A, but the exercise value is paid in currency B. For example, we could have an option on the USD-denominated S&P index $I(t)$ where the exercise value is GBP $c[I(T) - K]^+$. We can write the constant as $c = c_1 c_2$ where c_1 is the conventional dollar value of an index point, while c_2 is an exchange rate (the number of pounds per dollar). Thus a quanto option is a combination of a “foreign”-denominated option plus an exchange-rate guarantee. Valuation amounts to deriving the state-price density applicable to a market model including foreign as well as domestic assets.

Russian

A Russian option is a perpetual lookback option, that is, an American lookback option with no final maturity time.

MARK H.A. DAVIS

Option Pricing: General Principles

Option contracts are financial assets that involve an element of choice for the owner. Depending on an event, the holder of an option contract can exercise his/her options stated in the contract, that is, to undertake certain specified actions. The typical example of an option contract gives the holder the right to buy a specific stock at a contracted price and time in the future. The contracted price is called the *strike price*, whereas the exercise time is when the option may be executed. Such contracts are known as *call options*, and the event that triggers the execution of the option is that the underlying stock price is above the strike. There is a plethora of different options traded in today's modern financial markets, where the financial events may include **credit**, **weather** related situations, and so on. One usually refers to derivatives or claims as being financial assets whose values are dependent on other financial assets.

There are two fundamental questions that the option pricing theory tries to answer. First, what is the fair price of a claim, and second, how can one replicate the claim. The second question immediately implies the answer to the first, since if we can find an investment strategy in the market that replicates the claim, the cost of this replication should be the fair price. This replication strategy is frequently called the **hedging strategy** of the claim. The key financial concepts in pricing and replication are **arbitrage** (or rather the absence of such) and **completeness**. A mathematical concept related to these is the **equivalent martingale measure**, also known as the *risk-neutral probability*.

Explaining the Basic Concepts

To understand the concepts used, it is informative to consider a very simple (and highly unrealistic) one-period **binomial model**. Suppose that we have a stock with value \$100 today and two possible outcomes in one year. Either the stock price can increase to \$110 or it can remain unchanged. The interest rate earned on bank deposits is set to 5% yearly and considered the risk-free investment in the market.

Suppose that we wish to find a fair price of a call option with strike \$105 in one year. This option will effectively pay out \$5 if the stock increases, whereas the holder will not exercise it if the stock value is \$100. Consider now an investment today in $a = 0.5$ number of stocks and $b = -\$50/1.05 \approx -\47.62 deposited in the bank. A simple calculation reveals that this investment yields exactly the same as holding the option. In fact, this is the only investment in the stock and bank that perfectly replicates the option payoff and we, therefore, call it the *replicating strategy of the option*. The cost of replication is $P = \$50/21 \approx \2.38 .

We argue that the fair price of the option should be the same as the costs P of buying the replicating strategy. If the price would be higher, say $\tilde{P} > P$, then one could do the following. Sell n options for that price and buy n of the replicating strategy. At exercise, any claims from the options sold will be covered exactly by the replicating strategies bought. However, we have received the cash amount of $n \times \tilde{P}$ for selling the options and paid out the amount $n \times P$ for replication, thus leaving us with a profit. There is no risk attached with this investment proposition, and we can make the profit arbitrarily high by simply increasing n . This is what is known as an **arbitrage opportunity**, and in **efficient markets**, this should not be possible (or at least be ruled out quickly). If $\tilde{P} < P$, we reverse the positions above to create an arbitrage. The definition of a fair price is the price for which no arbitrage possibility exists. Thus, the option price in our example must be $P = \$50/21 \approx \2.38 .

We note that the probability of a stock price increase did not enter into our analysis. The fair price is unaffected by this probability, since the hedging strategy is the same no matter how likely the stock price is to increase to \$110. The price of the option does not depend on the expected return of the stock, but only on the spread in the two possible outcomes of the stock price at exercise time, or, in other words, the **volatility**.

One may ask if the price of an option can be stated as the present expected value of the payoff at exercise. From the above derivations, we see that this is, in general, not the case since the price is not a function of the probability of a stock price increase. Hence, a present value price of the option would lead to arbitrage possibilities. However, we may rephrase the question and ask whether *there exists* a probability q for price increase such that the fair price can be

expressed as a present value? Letting $q = 0.5$, we can easily convince ourselves that

$$\begin{aligned} P &= \frac{1}{1.05} \{q \times 5 + (1 - q) \times 0\} \\ &= \frac{1}{1.05} \mathbb{E}_q[\text{option payoff}] \end{aligned} \quad (1)$$

where $\mathbb{E}_q$ is the expectation with respect to the probability q . This probability of a stock price increase is *not* the probability for a price increase observed in the market, but a *constructed* probability for which the option price can be expressed as a present expected value.

The probability q has an interesting property that actually defines it. The present expected value of the stock price is equal to today's value,

$$100 = \frac{1}{1.05} \mathbb{E}_q[\text{stock price}] \quad (2)$$

Hence, the discounted stock price is a **martingale** with respect to the probability q . Further, the return on an investment in the stock coincides with the risk-free rate under q , defending the name “risk-neutral probability” often assigned to q .

Option Pricing in Continuous Time

Our binomial one-period example basically contains the main concepts for pricing of options and claims in more general and realistic market models. Moving to a stock price that evolves dynamically in time with stochastic marginal changes, the principles of option pricing remain basically the same, however, introducing interesting technical challenges. We now look at the case when the stock price follows a **geometric Brownian motion** (GBM), that is,

$$\frac{dS(t)}{S(t)} = \mu dt + \sigma dB(t) \quad (3)$$

defined on a probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$ with the filtration $\mathcal{F}_t$ generated by the Brownian motion modeling the information flow. The GBM model indicates that returns (or more precisely, logarithmic returns) are independent and normally distributed, with mean μdt and volatility $\sigma\sqrt{dt}$. The model was first proposed for stock price dynamics by **Samuelson** [7] and later used by **Black and Scholes** [1] and **Merton** [6] in their derivation of the

famous **option pricing formula**. We suppose that the market is frictionless in the sense that there are no transaction costs incurred when we trade in the stock or the bank, and there are no restrictions on short or long positions. Further, the interest rate is the same whether we borrow or lend money, and the market is perfectly liquid.

The main difference from the one-period model is that we can invest in the underlying stock at all times up to maturity of the claim. Obviously, we can also do the same with the bank deposit, which is now assumed to yield a continuously compounding interest rate r . An investment strategy will consist of $a(t)$ shares of the stock and $b(t)$ invested in the bank at time t . Since investors cannot foresee the future, the investment decisions at time t can only be based upon the available market information, which is contained in the filtration $\mathcal{F}_t$. The value at time t of the portfolio is

$$V(t) = a(t)S(t) + b(t)R(t) \quad (4)$$

where $R(t) = \exp(rt)$, the value of an initial bank deposit of 1. Further, since we are interested in creating strategies that are replicating an option, we wish to rule out any external funding or withdrawal of money in the portfolio we are setting up. This leads to the so-called **self-financing** hypothesis, saying that any change in portfolio value comes from a change in the underlying stock price and bank deposit. Mathematically, we can formulate this condition as

$$dV(t) = a(t) dS(t) + b(t) dR(t) \quad (5)$$

Note that **Itô's formula** implies a dynamics $V(t)$ where the differentials of $a(t)$ and $b(t)$ appear. The self-financing hypothesis indicates that these differentials are zero.

For the one-period binomial model, we recall the existence of an **equivalent martingale measure** for which the discounted stock price is a martingale. Applying the Girsanov theorem, we find a probability measure $\mathbb{Q}$ **equivalent** to the market probability $\mathbb{P}$, for which the process $W(t)$ with differential

$$dW(t) = \frac{\mu - r}{\sigma} dt + dB(t) \quad (6)$$

is a Brownian motion. By a direct calculation, we find

$$d(e^{-rt} S(t)) = \sigma(e^{-rt} S(t)) dW(t) \quad (7)$$

which is a **martingale** under $\mathbb{Q}$. Furthermore, by discounting the portfolio process $V(t)$ and applying the self-financing hypothesis, we find

$$d(e^{-rt} V(t)) = \sigma a(t)(e^{-rt} S(t)) dW(t) \quad (8)$$

Hence, the discounted portfolio process is also a martingale under $\mathbb{Q}$.

Consider a claim with maturity at time T and a payoff represented by the random variable X , where $\mathcal{F}_T$ is measurable and integrable with respect to $\mathbb{Q}$. The (for the moment unknown) price at time t of the claim is denoted by $P(t)$. Suppose that the discounted price of the claim is a martingale with respect to $\mathbb{Q}$ and that we have a self-financing portfolio consisting of investments in the stock, the bank notes, and the claim. Further, we construct the investment such that the initial price is zero. The discounted value process of this portfolio will then (by the same reasoning as above) give a martingale process under $\mathbb{Q}$, and hence the expectation with respect to $\mathbb{Q}$ of the portfolio value at any future time must be the same as the initial investment, namely, zero. Thus, under $\mathbb{Q}$, there is a positive probability of having a negative portfolio value, which implies by equivalence of $\mathbb{Q}$ with $\mathbb{P}$ that we cannot have any arbitrage opportunities in this market. On the other hand, if the market does not allow for any arbitrage, one can show that $e^{-rt} P(t)$ must be a $\mathbb{Q}$ -martingale. We refer to [3] for the connection between no-arbitrage and existence of equivalent martingale measures. It is a financially reasonable condition to assume that the market is arbitrage free.

By the **martingale representation theorem**, there exists an **adapted** stochastic process $\phi(t)$ such that

$$d(e^{-rt} P(t)) = \phi(t) dW(t) \quad (9)$$

whenever $\exp(-rt)P(t)$ is square-integrable with respect to $\mathbb{Q}$. By defining $a(t) \triangleq \phi(t)/\sigma \exp(-rt)S(t)$ and $b(t) \triangleq \exp(-rt)(P(t) - a(t)S(t))$, the portfolio $V(t)$ given by the investment strategy (a, b) is self-financing. Moreover, $V(T) = P(T) = X$, implying that it is a replicating strategy for the claim. Furthermore the market becomes **complete**, meaning that there exists a replicating strategy for all claims, X being square-integrable with respect to $\mathbb{Q}$.

Now, again appealing to the $\mathbb{Q}$ -martingale property of $e^{-rt} P(t)$, we find by definition that

$$P(t) = e^{-r(T-t)} \mathbb{E}_{\mathbb{Q}}[X | \mathcal{F}_t] \quad (10)$$

Thus, as a natural generalization of the binomial one-period model case, any claim has a price given as the expected present value, where the expectation is taken with respect to the risk-neutral probability. Note that S does not depend on its expected return μ under $\mathbb{Q}$, and therefore the price $P(t)$ is independent of this. The volatility σ is, however, a crucial parameter for the determination of price.

If we let X be the payoff of a call option written on S , one can calculate the conditional expectation in equation (10) to derive the famous **Black–Scholes formula**. Further, the process $\phi(t)$ is in this case explicitly known, and it turns out that the investment strategy $a(t)$ is the derivative of the price $P(t)$ with respect to $S(t)$. This derivative is known as the delta of the call option. Moreover, the strategy given by $a(t)$ is called *delta-hedging*.

Option Pricing in Incomplete Markets

Recall that we have assumed a frictionless market. In practice, transaction costs are normally incurred when buying and selling shares. Hence, since a delta-hedging strategy (a, b) involves incessant trading, it will become infinitely costly if implemented. In addition, there are practical limits to how big a short position we can take (e.g., due to credit limits and collaterals). Theoretically, there exists only *one* replicating strategy since the martingale representation theorem prescribes a unique integrand process $\phi(t)$. Introducing frictions such as transaction costs or short-selling limits in the market rules out the possibility to replicate claims in general, and the market is said to be **incomplete**. We remark that in an incomplete market, there still exists claims that can be replicated, and by the no-arbitrage principle, the price of these is characterized by the cost of replication, as we have argued above. However, a natural question arises: what can we say about pricing and hedging of claims where no replicating strategy exists?

One approach suggests to look at **super- and sub-replicating strategies**. A super(sub-)replicating strategy is a self-financing portfolio of stock and bank deposit, which at least(most) has the same value as the claim at maturity. Letting $P_{\max}$ ($P_{\min}$) be the infimum (supremum) over all prices of such super(sub-)replicating strategies, it follows that any price P in the interval $(P_{\min}, P_{\max})$ is arbitrage

free. Furthermore, any self-financing strategy that costs less than $P_{\max}$ will always have a positive probability of having a value lower than the claim at maturity, and thus full replication is impossible. This leaves the issuer of the claim with some unhedgable risk. An acceptable or fair price of the claim will reflect the compensation the issuer demands for taking on this risk.

A change in the stock price dynamics gives another source of incompleteness in the market. The GBM model is rather unnatural from an empirical point of view, since observed stock price returns on the marketplace are frequently far from being normally distributed nor are they independent. Stock price models including **stochastic volatility** and/or stochastic drivers other than Brownian motion have been proposed. For instance, on the basis of empirics, the returns may be modeled by a heavy-tailed distribution, which gives rise to a **Lévy process** in the geometric dynamics of the stock price. A consequence of such a seemingly innocent change in the structure is that there exists a continuum (in general) of **equivalent martingale measures** $\mathbb{Q}$ such that the discounted stock price is a martingale. The complicating implication of this is the absence of martingale representations when it becomes impossible to find an investment strategy replicating the claim. As for markets with frictions, we have no possibility of replication, but an interval of possible arbitrage-free prices. In addition, in this case, the issuer of the claim needs to accept a certain unhedgable risk.

To price claims in incomplete markets, one must resort to methods that take into account the risk posed on the issuer. Popular approaches include minimal-variance hedging, where the strategy minimizing the variance (that is, the risk) is sought for. The price of the claim is the cost of buying the minimal-variance strategy [8] plus a compensation for the unhedged risk. Another possibility that has gained a lot of attention in the option pricing literature is **indifference pricing** (see also the seminal work of Hodges and Neuberger [5]). Here, one considers an investor who has two opportunities. Either he/she can invest his/her funds in the market, or he/she can sell a claim and invest his/her funds along with claim price. In the latter case, he/she has more funds for investment, but on the other hand, he/she faces a claim at maturity. By optimizing his/her expected

utility from the two investment scenarios, the *indifference price* of the claim is defined as the price that makes one indifferent between the two opportunities. The choice of an exponential utility function leads to prices where the singular case of zero risk aversion coincides with the price defined by the **minimal entropy martingale measure** [4]. This price lends itself to the interpretation of being the price that is equally desirable for both the issuer and the buyer in the case when both parties have zero risk aversion. For all other risk aversions, the seller will charge higher prices, and the buyer will demand lower. The difference of the two optimal investment strategies obtained from utility maximization becomes the hedging strategy. This and other similar approaches have gained a lot of academic attention in the recent years.

Another path to pricing in incomplete markets is to try to complete the market by adding options. The required number of options to complete the market is closely linked to the number of sources of uncertainty and the number of assets. For example, considering a GBM with a stochastic volatility following the Heston model gives two random sources and one asset. Following the analysis in [2], one call option is sufficient to complete the market. In [2], the necessary and sufficient conditions to complete markets are given in the case when the filtration is spanned by more Brownian motions than there are traded assets.

Forwards and Futures

Futures and forwards are financial contracts that make it possible to reduce the price risk that arises from the intention to buy or sell certain assets at a later date. A forward contract specifies in advance the price that will be paid at such a later date for the delivery of the asset. This obviously reduces the price risk for that transaction to zero for all parties involved. A futures contract, on the other hand, guarantees that changes in the asset's price that occur before the delivery date will be compensated for immediately when they arise. This compensation is achieved by offsetting payments into a bank account that is called the *margin account*. This significantly reduces the price risk associated with the futures transaction, since the only possible remaining source of uncertainty is now due to the interest rate used for the margin account.

The assets that are bought or sold at the delivery date can be storable commodities (such as gold, oil, and agricultural products), nonstorable commodities (such as electricity), or other financial assets (such as stocks, bonds, options, or currencies). Forward contracts are also used by parties to agree in advance on an interest rate that will be paid or charged during a later time period, in so-called forward rate agreements (FRAs). Similarly, one can buy and sell futures on the value of money deposited in a bank account. For such interest rate futures, which include the very popular eurodollar and euribor contracts, there is no actual delivery but the contract is fulfilled by cash settlement instead.

Here, we discuss only the general pricing principles for forwards and futures. We refer to other articles in the encyclopedia for detailed information concerning the delivery procedures and methods to quote prices for specific futures and forward contracts, such as eurodollar futures (*see Eurodollar Futures and Options*), forward rate agreements (*see LIBOR Rate*), electricity (*see Electricity Forward Contracts*), commodity (*see Commodity Forward Curve Modeling*), and foreign exchange forwards (*see Currency Forward Contracts*).

Using Futures and Forwards

Forward contracts are usually agreed upon by two parties who directly negotiate the terms of such contracts, which can therefore be very flexible. The two

parties need to agree on the specific asset (often called *the underlying asset*) and on the precise quantities that are bought or sold, on the exact date when the transactions take place (the *delivery date*), and the price that will be charged on that date (the *forward price*). Usually the forward price is chosen in such a way that both parties agree to sign the contract without any money changing hands before the delivery date. This implies that the forward contract starts with having zero market value, since both parties are willing to sign it without receiving or paying any money for it. Later on, the contract may have a positive or negative market value, since every change in the market price of the underlying asset will make the existing agreement as written in the contract more beneficial to one of the parties and less beneficial to the other one. The forward contract may, therefore, become a serious liability for one of the two parties involved, so there is the risk that this party is no longer willing or able to honor the terms of the contract on the delivery date. This counterparty risk problem can be avoided by the use of futures contracts.

Futures are standardized contracts that are traded on futures exchanges. When entering a futures contract, a margin account on the futures exchange is opened and a payment into that account is required, to make it possible for the exchange to withdraw money when appropriate. The exchange publishes a *futures price* for every contract, which is updated regularly to reflect price changes in the underlying. Whenever a new futures price is announced, an amount of cash that is equal to the difference between the new futures price and the previous one is paid into or withdrawn from the margin account, depending on whether one is *short* the contract or *long* the contract. Parties that intend to buy the underlying are long the contract, and they, therefore, receive money if the futures price goes up and pay when it goes down. Parties that intend to sell are short the contract, and they, therefore, pay money if the futures price goes down and receive money when it goes up. This procedure is known as *marking to market*. Since on the delivery date the futures price is always equal to the underlying asset price, a possible difference between the initial futures price and the current asset price has been compensated for by the intermediate payments into the margin account.

Parties with opposite positions in the futures market deal only with the exchange instead of with each other, which explains the need for standardized

contracts and the significant reduction in counterparty risk. Since no cash is needed to enter into a new (long or short) futures contract as long as there is enough money left in the margin account, it is easy to change a position in futures once such an account has been established. One can terminate existing long contracts by simply taking a position in offsetting short contracts or *vice versa*, and many parties close their position just before the delivery date if they are only interested in compensation for price changes and not in the actual delivery. This makes futures very convenient to use for hedging purposes (*see Hedging*) and for speculation on an underlying's price movements. Likewise, it is quite easy for the exchange to close the futures position of a party who refuses to put more money in their margin account when asked to do so in the so-called margin call.

These characteristics have made futures very popular financial instruments and the market for them is huge. In 2008, more than eight billion futures contracts were traded worldwide with underlying assets^a in equity indices (37%), individual equity (31%), interest rates (18%), agricultural goods (5%), energy (3%), currencies (3%), and metals (2%). The most popular are contracts on the S&P 500 and Dow Jones indices, followed by eurodollar and eurobund futures, and contracts on white sugar, soybeans, crude oil, aluminum, and gold. The notional amounts underlying futures on interest rates, equity indices, and currencies at the world's exchanges were estimated to be 27 trillion, 1.6 trillion, and 175 billion US dollars, respectively, in June 2008^b.

Pricing Methods for Forwards in Discrete Time

To analyze the futures and forward prices, we first look at discrete-time models, and then look at generalizations in continuous time.

Consider a discrete-time market model on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with a filtration $(\mathcal{F}_n)_{n \in \mathcal{N}}$ where $\mathcal{N} = \{0, 1, \dots, N\}$ denotes our discrete-time set. We define assets S and B to model the underlying asset and a bank account, respectively, with associated stochastic price processes $(S_n)_{n \in \mathcal{N}}$ and $(B_n)_{n \in \mathcal{N}}$. We assume that S is adapted and that B is predictable with respect to this filtration, and that both B and $1/B$ are bounded. Associated with the asset S are cash flows $(D_n)_{n \in \mathcal{N}}$ where D_n denotes the sum of all cash flows caused by holding one unit of S at

time n . These cash flows can be positive (such as dividends when S is a stock, or interest when S is a currency) or negative (such as storage costs when S is a commodity). We will always assume perfect market liquidity (*see Liquidity*), so all assets can be bought and sold in all possible quantities for their current market prices and no transaction costs (*see Transaction Costs*) are charged.

The cash flows associated with a forward contract that is initiated at time $T_0 \in \mathcal{N}$ take place at the time of delivery $T_d \in \mathcal{N}$ that is specified in the contract, with $T_0 \leq T_d$. At time T_d , the asset is delivered while the forward price agreed upon at the initial time T_0 for delivery at time T_d , which we denote by $F(T_0, T_d)$, is paid in return. Since this forward price needs to be determined at time T_0 , it should be $\mathcal{F}_{T_0}$ -measurable. Moreover, the forward price is chosen in such a way that both parties agree to enter the contract without any cash changing hands at this initial time.

In complete and arbitrage-free markets (*see Arbitrage Pricing Theory*), it is often possible to find an explicit expression for the forward price $F(T_0, T_d)$, since the cash flows associated with the contract can then be replicated using other assets with known prices. Let us assume that there exists a unique martingale measure $\mathbb{Q}$, which is equivalent to $\mathbb{P}$, such that the discounted versions of tradable assets are martingales under this measure (*see Equivalent Martingale Measures*). This is almost equivalent to the assumption of a complete and arbitrage-free market; for the exact statement (*see Fundamental Theorem of Asset Pricing*). Contingent claims that pay a cash-flow stream of $\mathcal{F}_n$ -measurable amounts X_n at the times $n \in \mathcal{N}$ in such markets have a unique price p at time $k \in \mathcal{N}$ equal to

$$p_k = \sum_{n \in \mathcal{N}, n \geq k} B_k \mathbb{E}^{\mathbb{Q}}[X_n / B_n \mid \mathcal{F}_k] \quad (1)$$

A specific example is the zero-coupon bond price at time k for the delivery of one unit cash at time $T > k$, which is equal to $p(k, T) = B_k \mathbb{E}^{\mathbb{Q}}[1/B_T \mid \mathcal{F}_k]$.

Suppose that an investor enters into a forward contract at time T_0 , which obliges him/her to deliver the underlying asset S at time T_d , and that he/she buys the underlying asset at time T_0 to hold it until delivery. This will lead to a cashflow of $-S_{T_0}$ at time T_0 , to cash flows D_n at times $\{n \in \mathcal{N} : T_0 \leq n \leq T_d\}$, and a cash flow of $F(T_0, T_d)$ at time T_d when he/she delivers the asset. Since a forward contract is entered

into without any money changing hands and since the net position after delivery will be zero, the value of the cash-flow stream defined above must be zero if there is no arbitrage in the market. Using the previous equation, we thus find that

$$0 = -S_{T_0} + B_{T_0} \mathbb{E}^{\mathbb{Q}}[F(T_0, T_d)/B_{T_d} | \mathcal{F}_{T_0}] + \sum_{T_0 \leq n \leq T_d} B_{T_0} \mathbb{E}^{\mathbb{Q}}[D_n/B_n | \mathcal{F}_{T_0}] \quad (2)$$

Since $F(T_0, T_d)$ is $\mathcal{F}_{T_0}$ -measurable, this leads to the following expression for a forward price in a complete and arbitrage-free market:

$$\begin{aligned} F(T_0, T_d) &= \frac{S_{T_0}/B_{T_0} - \sum_{T_0 \leq n \leq T_d} \mathbb{E}^{\mathbb{Q}}[D_n/B_n | \mathcal{F}_{T_0}]}{\mathbb{E}^{\mathbb{Q}}[1/B_{T_d} | \mathcal{F}_{T_0}]} \\ &= \frac{S_{T_0} - B_{T_0} \sum_{T_0 \leq n \leq T_d} \mathbb{E}^{\mathbb{Q}}[D_n/B_n | \mathcal{F}_{T_0}]}{p(T_0, T_d)} \end{aligned} \quad (3)$$

In particular, when there are no dividends or storage costs, the forward price is simply equal to the current price of the underlying asset divided by the appropriate discount rate until delivery. For commodities, where the cash flows D_n are often negative since they represent storage costs, this formula (3) is known as the *cost-of-carry formula*. Conversely, when the actual possession of an underlying asset is more beneficial than just holding the forward contract, this can be modeled by introducing positive cash flows D_n . Such benefits are often expressed as a rate, the so-called convenience yield, which may fluctuate as a result of changing expectations concerning the availability of the underlying asset on the delivery date.

The initial price of a forward contract is zero, but when the underlying asset's price changes, so does the value of an existing contract. If we denote by $G(T_0, T_d, k)$ the value at time k of a forward contract entered at time $T_0 \leq k$ for delivery at time $T_d \geq k$, then a similar argument as before leads to

$$\begin{aligned} G(T_0, T_d, k) &= B_k \mathbb{E}^{\mathbb{Q}} \left[\frac{F(k, T_d) - F(T_0, T_d)}{B_{T_d}} | \mathcal{F}_k \right] \\ &= p(k, T_d) (F(k, T_d) - F(T_0, T_d)) \end{aligned} \quad (4)$$

Pricing Methods for Futures in Discrete Time

All cash flows associated with a futures contract take place *via* the margin account. Let $(M_n)_{n \in \mathcal{N}}$ be the process describing the value of the margin account associated with a long position in one future on the underlying asset S defined above. If $f(k, T_d)$ is the futures price at time k for delivery of one unit of the asset at time $T_d > k$ ($k, T_d \in \mathcal{N}$), then the margin account values will satisfy

$$M_{k+1} = \frac{B_{k+1}}{B_k} M_k + f(k+1, T_d) - f(k, T_d) \quad (5)$$

where we assume that the interest rate used for the margin account is the same as the one used for B .

Futures prices are determined by supply and demand on the futures exchanges, but if we assume a complete and arbitrage-free market for S and B , we can derive a theoretical formula for the futures price. We consider an investment strategy where at a certain time $k \in \mathcal{N}$, we open a new margin account, put an initial margin amount M_k into it, and take a long position in a futures contract for delivery at time T_d . One time step later, we go short one future contract for the same delivery date, which effectively closes our futures position, and we then empty our margin account. Since our net position is then zero again and since we do not pay or receive money to go long or short a futures contract, the total value of this cash-flow stream at time k should be equal to zero, so

$$\begin{aligned} 0 &= -M_k + B_k \mathbb{E}^{\mathbb{Q}} \left[\frac{M_{k+1}}{B_{k+1}} | \mathcal{F}_k \right] \\ &= B_k \mathbb{E}^{\mathbb{Q}} \left[\frac{f(k+1, T_d) - f(k, T_d)}{B_{k+1}} | \mathcal{F}_k \right] \end{aligned} \quad (6)$$

Since B was assumed to be predictable, that is, B_{k+1} is $\mathcal{F}_k$ -measurable for all $k \in \mathcal{N} \setminus \{N\}$, we may conclude from the above that the futures price process $f(\cdot, T_d)$ is a $\mathbb{Q}$ -martingale for any fixed delivery date $T_d \in \mathcal{N}$, and hence

$$f(k, T_d) = \mathbb{E}^{\mathbb{Q}}[S_{T_d} | \mathcal{F}_k] \quad (7)$$

since $f(T_d, T_d) = S_{T_d}$. Note that this formula no longer holds if B fails to be predictable or when the interest rates paid on the bank account B and the margin account M are different.

Continuous-time Models

The generalization to continuous-time models is rather straightforward for forward contracts, but more subtle for futures contracts.

Assume that the price process of the underlying asset is a stochastic process S on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with a filtration $(\mathcal{F}_t)_{t \in [0, T]}$ that satisfies the usual conditions, that is, it is right continuous and $\mathcal{F}_0$ contains all $\mathbb{P}$ -null sets. We will assume that the process S is an adapted semimartingale and that the bank account process B is an adapted and predictable semimartingale, and B and $1/B$ are assumed to be bounded almost surely. We model the dividend and storage costs of the asset S using an adapted semimartingale D , with the interpretation that the total amount of dividends received minus the storage costs paid between two times t_1 and t_2 is equal to $D_{t_2} - D_{t_1-}$ where $0 \leq t_1 < t_2 \leq T$.

To determine the correct forward price $F(T_0, T_d)$ for a forward contract initiated at time T_0 for delivery at time T_d , we follow the same arguments as in the discrete-time case. If we borrow money to buy the underlying asset today and then hold on to it until we deliver it at the delivery date in return for a payment of the forward price, the total value of this cash-flow stream should be zero since we enter the forward contract without any cash payments. Therefore, p_t should be zero in the formula above if we substitute $t = T_0$ and the cash-flow stream

$$\begin{aligned} X_t &= 0, \quad (t < T_0, t > T_d), \quad X_{T_0} = -S_{T_0}, \\ X_t &= D_t \quad (t \in]T_0, T_d[), \quad X_{T_d} = D_{T_d} + F(T_0, T_d) \end{aligned} \quad (9)$$

Using the fact that the forward price $F(T_0, T_d)$ must be $\mathcal{F}_{T_0}$ -measurable then leads to

$$F(T_0, T_d) = \frac{1}{p(T_0, T_d)} \left(S_{T_0} - B_{T_0} \mathbb{E}^{\mathbb{Q}} \left[\int_{T_0}^{T_d} \left(\frac{dD_u}{B_{u-}} + d \left[D, \frac{1}{B} \right]_u \right) \middle| \mathcal{F}_{T_0} \right] \right) \quad (10)$$

As in the discrete-time case, we assume that we have a complete and arbitrage-free market and that there exists a unique measure $\mathbb{Q}$ that is equivalent to $\mathbb{P}$ such that discounted versions of tradable assets become martingales under this measure (*see Equivalent Martingale Measures*). We model contingent claims by a cumulative cash-flow stream $(X_t)_{t \in [0, T]}$, which is an adapted semimartingale. The total cash amount paid out by the contingent claim between two times t_1 and t_2 is given by $X_{t_2} - X_{t_1-}$, and $X_t - X_{t-}$ corresponds to a payment at the single time t (with $t, t_1, t_2 \in [0, T]$ and $t_2 \geq t_1$). Such contingent claims have a unique price p in a complete and arbitrage-free market, which at time t is equal to

$$p_t = B_t \mathbb{E}^{\mathbb{Q}} \left[\int_t^T \left(\frac{dX_u}{B_{u-}} + d \left[X, \frac{1}{B} \right]_u \right) \middle| \mathcal{F}_t \right] \quad (8)$$

The last term involving the brackets compensates for the fact that the cash flows X and the bank account may have nonzero covariation, so it disappears when B has finite variation and is continuous, or when B is deterministic. Compare this to the discrete-time case, where we assumed that $(B_n)_{n \in \mathbb{N}}$ is predictable.

The formula for the value of a forward contract at a later time after T_0 is the same as in the discrete-time case.

We now turn to the definition of a futures price process $(f(t, T_d))_{t \in [0, T_d]}$ in continuous time for delivery at a fixed time $T_d \in [0, T]$. Let $(\psi_t)_{t \in [0, T_d]}$ be a futures investment strategy: a bounded and predictable stochastic process such that ψ_t represents the number of futures contracts (positive or negative) we own at time t . The associated margin account process $(M_t)_{t \in [0, T]}$ is then defined on $[0, T]$ as

$$dM_t = M_t \frac{dB_t}{B_{t-}} + \psi_t df(t, T_d) \quad (11)$$

with $M_0 \in \mathbb{R}$, where we have again assumed that the margin account earns the same interest rate as the bank account B . As mentioned before, the futures price process should be equal to the underlying asset price at delivery, so $f(T_d, T_d) = S_{T_d}$.

In a complete and arbitrage-free market, we consider an investment strategy where at any time $t \in [0, T_d]$ we open a new margin account and put an initial margin amount M_t in, go long one future contract at time t , wait until a later date $s \in]t, T_d]$ and

close our futures position by going short one contract, and close our margin account. If there is no arbitrage, the discounted value of the cash flows from this strategy should be zero at time t since we start and end without any position, so

$$M_t = B_t \mathbb{E}^{\mathbb{Q}} \left[\frac{M_s}{B_s} \middle| \mathcal{F}_t \right] \quad (12)$$

This shows that M/B is a martingale under $\mathbb{Q}$, that is, the margin account should be a tradable asset. A bit of stochastic calculus shows that

$$d \left(\frac{M_t}{B_t} \right) = \frac{df(t, T_d)}{B_{t-}} + d \left[f(\cdot, T_d), \frac{1}{B} \right]_t \quad (13)$$

and we see that if B is continuous, of finite variation, bounded, and bounded away from zero, then the futures price process $f(\cdot, T_d)$ is itself a martingale under $\mathbb{Q}$ and hence

$$f(t, T_d) = \mathbb{E}^{\mathbb{Q}} [f(T_d, T_d) \mid \mathcal{F}_t] = \mathbb{E}^{\mathbb{Q}} [S_{T_d} \mid \mathcal{F}_t] \quad (14)$$

Note that in this case the difference between the forward and futures prices can be expressed as

$$\begin{aligned} F(t, T_d) - f(t, T_d) &= \frac{B_{T_0}}{p(T_0, T_d)} \left(\mathbb{E}^{\mathbb{Q}} \left[\frac{S_{T_d}}{B_{T_d}} \middle| \mathcal{F}_{T_0} \right] \right. \\ &\quad \left. - \mathbb{E}^{\mathbb{Q}} [S_{T_d} \mid \mathcal{F}_{T_0}] \mathbb{E}^{\mathbb{Q}} \left[\frac{1}{B_{T_d}} \middle| \mathcal{F}_{T_0} \right] \right) \end{aligned} \quad (15)$$

Since the expression in brackets is the $\mathcal{F}_{T_0}$ -conditional covariance between S_{T_d} and $1/B_{T_d}$, we immediately see that forward and futures prices coincide if and only if these two stochastic variables are uncorrelated when conditioned on $\mathcal{F}_{T_0}$, for example, when the bank account B is deterministic.

Extensions

For clarity of exposition, we have focused here on forward and future prices in complete and arbitrage-free markets without transaction costs (see **Transaction Costs**). Early papers on the theoretical pricing methods are by Black [3] for deterministic interest rates and Cox *et al.* [5] and Jarrow and Oldfield [9] for the general case. Continuous resettlement is

treated by Duffie and Stanton [7] and Karatzas and Shreve [10], see also [12]. See [2] for a very clear summary of the principles involved. For excellent introductions to the practical organization of futures and forward markets and for empirical results on prices, the books by Duffie [6], Hull [8], and Kolb [11] are recommended.

For incomplete markets, there is a theory of equilibrium in futures market under mean–variance preferences; see, for example, [14] and the consumption-based capital asset pricing model of Breeden [4] (see also **Capital Asset Pricing Model**). Many futures allow a certain flexibility regarding the exact product that must be delivered and regarding the time of delivery. The value of this last “timing option” is analyzed in a paper by Biagini and Björk [1].

When the bank account process B is not of finite variation and continuous, the futures price is no longer a martingale under $\mathbb{Q}$; however under some technical conditions, it can be shown to be a martingale under another equivalent measure that can be found using a multiplicative Doob–Meyer decomposition (see **Doob–Meyer Decomposition**) as shown in [15]. The assumption that B and $1/B$ are bounded is often too restrictive in practice; see [13] for weaker conditions.

MICHEL VELLEKOOP

Black–Scholes Formula

“If options are correctly priced in the market, it should not be possible to make sure profits by creating portfolios of long and short positions in options and their underlying stocks. Using this principle, a theoretical valuation formula for options is derived.” These sentences, from the abstract of the great paper [2] by Fischer Black and Myron Scholes, encapsulate the basic idea that—with the asset price model they employ—insisting on absence of **arbitrage** is enough to obtain a unique value for a call option on the asset. The resulting formula, equation (6) below, is the most famous formula in financial economics, and, in fact, that whole subject splits decisively into the **pre-Black–Scholes** and post-Black–Scholes eras.

This article aims to give a self-contained derivation of the formula, some discussion of the hedge parameters, and some extensions of the formula, and to indicate why a formula based on a stylized mathematical model, which is known not to be a particularly accurate representation of real asset prices, has nevertheless proved so effective in the world of option trading. The section The Model and Formula formulates the model and states and proves the formula. As is well known, the formula can equally well be stated in the form of a partial differential equation (PDE); this is equation (9) below. The next section discusses the PDE aspects of Black–Scholes. The section Hedge Parameters summarizes information about the option ‘greeks’, while the sections The Black ‘Forward’ Option Formula and A Universal Black Formula introduce what is actually a more useful form of Black–Scholes, usually known as the *Black formula*. Finally, the section Implied Volatility and Market Trading discusses the applications of the formula in market trading. We define the *implied volatility* and demonstrate a “robustness” property of Black–Scholes, which implies that effective hedging can be achieved even if the “true” price process is substantially different from Black and Scholes’ stylized model.

The Model and Formula

Let $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \in \mathbb{R}^+}, \mathbb{P})$ be a **probability space** with a given filtration $(\mathcal{F}_t)$ representing the flow of

information in the market. Traded asset prices are $\mathcal{F}_t$ -adapted stochastic processes on $(\Omega, \mathcal{F}, \mathbb{P})$. We assume that the market is *frictionless*; assets may be held in arbitrary amount, positive and negative, the interest rate for borrowing and lending is the same, and there are no transaction costs (i.e., the bid–ask spread is 0). While there may be many traded assets in the market, we fix attention on two of them. First, there is a “risky” asset whose price process $(S_t, t \in \mathbb{R}^+)$ is assumed to satisfy the **stochastic differential equation** (SDE)

$$dS_t = \mu S_t dt + \sigma S_t dw_t \quad (1)$$

with given *drift* μ and *volatility* σ . Here $(w_t, t \in \mathbb{R}^+)$ is an $(\mathcal{F}_t)$ -Brownian motion. Equation (1) has a unique solution: if S_t satisfies equation (1), then by the **Itô formula**

$$d \log S_t = \left(\mu - \frac{1}{2}\sigma^2\right) dt + \sigma dw_t \quad (2)$$

so that S_t satisfies equation (1) if and only if

$$S_t = S_0 \exp\left(\left(\mu - \frac{1}{2}\sigma^2\right)t + \sigma w_t\right) \quad (3)$$

Asset S_t is assumed to have a constant *dividend yield* q , that is, the holder receives a dividend payment $qS_t dt$ in the time interval $[t, t + dt]$. Secondly, there is a riskless asset paying interest at a fixed continuously compounding rate r . The exact form of this asset is unimportant—it could be a money-market account in which \$1 deposited at time s grows to $\$e^{r(t-s)}$ at time t , or it could be a zero-coupon bond maturing with a value of \$1 at some time T , so that its value at $t \leq T$ is

$$B_t = \exp(-r(T - t)) \quad (4)$$

This grows, as required, at rate r :

$$dB_t = r B_t dt \quad (5)$$

Note that equation (5) does not depend on the final maturity T (the same growth rate is obtained from any zero-coupon bond) and the choice of T is a matter of convenience.

A *European call option* on S_t is a contract, entered at time 0 and specified by two parameters (K, T) , which gives the holder the right, but not the obligation, to purchase 1 unit of the risky asset at price K at time $T > 0$. (In the frictionless market setting, an option to buy N units of stock is equivalent

to N options on a single unit, so we do not need to include quantity as a parameter.) If $S_T \leq K$ the option is worthless and will not be exercised. If $S_T > K$ the holder can exercise his option, buying the asset at price K , and then immediately selling it at the prevailing market price S_T , realizing a profit of $S_T - K$. Thus, the exercise value of the option is $[S_T - K]^+ = \max(S_T - K, 0)$. Similarly, the exercise value of a *European put option*, conferring on the holder the right to *sell* at a fixed price K , is $[K - S_T]^+$. In either case, the exercise value is nonnegative and, in the above model, is strictly positive with positive probability, so the option buyer should pay the writer a premium to acquire it. Black and Scholes [2] showed that there is a unique arbitrage-free value for this premium.

Theorem 1

1. In the above model, the unique arbitrage-free value at time $t < T$ when $S_t = S$ of the call option maturing at time T with strike K is

$$C(t, S) = e^{-q(T-t)} SN(d_1) - e^{-r(T-t)} KN(d_2) \quad (6)$$

where $N(\cdot)$ denotes the cumulative standard normal distribution function

$$N(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-\frac{1}{2}y^2} dy \quad (7)$$

and

$$\begin{aligned} d_1 &= \frac{\log(S/K) + (r + \sigma^2/2)(T - t)}{\sigma\sqrt{T - t}} \\ d_2 &= d_1 - \sigma\sqrt{T - t} \end{aligned} \quad (8)$$

2. The function $C(t, S)$ may be characterized as the unique $C^{1,2}$ solution^a of the Black–Scholes PDE

$$\frac{\partial C}{\partial t} + rS \frac{\partial C}{\partial S} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 C}{\partial S^2} - rC = 0 \quad (9)$$

solved backward in time with the terminal boundary condition

$$C(T, S) = [S - K]^+ \quad (10)$$

3. The value of the put option with exercise time T and strike K is

$$\begin{aligned} P(t, S) &= e^{-r(T-t)} KN(-d_2) \\ &\quad - e^{-q(T-t)} SN(-d_1) \end{aligned} \quad (11)$$

To prove the theorem, we are going to show that the call option value can be replicated by a dynamic trading strategy investing in the asset S_t and in the zero-coupon bond $B_t = e^{-r(T-t)}$. A trading strategy is specified by an initial capital x and a pair of adapted processes α_t, β_t representing the number of units of S, B respectively held at time t ; the portfolio value at time t is then $X_t = \alpha_t S_t + \beta_t B_t$, and by definition $x = \alpha_0 S_0 + \beta_0 B_0$. The trading strategy (x, α, β) is *admissible* if

- (i) $\int_0^T \alpha_t^2 S_t^2 dt < \infty$ a.s.
 - (ii) $\int_0^T |\beta_t| dt < \infty$ a.s.
 - (iii) There exists a constant $L \geq 0$ such that $X_t \geq -L$ for all t , a.s.
- (12)

The *gain from trade* in $[s, t]$ is

$$\int_s^t \alpha_u dS_u + \int_s^t \beta_u dB_u + \int_s^t q\alpha_u S_u du$$

where the first integral is an Itô stochastic integral. This is the sum of the accumulated capital gains/losses in the two assets plus the total dividend received. The trading strategy is *self-financing* if

$$\begin{aligned} &\alpha_t S_t + \beta_t B_t - \alpha_s S_s - \beta_s B_s \\ &= \int_s^t \alpha_u dS_u + \int_s^t q\alpha_u S_u du + \int_s^t \beta_u dB_u \end{aligned} \quad (13)$$

implying that the change in value over any interval in portfolio value is entirely due to gains from trade (the accumulated increments in the value of the assets in the portfolio plus the total dividend received).

We can always create self-financing strategies by fixing α , the investment in the risky asset, and investing all residual wealth in the bond. Indeed, the value of the risky asset holding at time t is $\alpha_t S_t$, so if the total portfolio value is X_t we take

$\beta_t = (X_t - \alpha_t S_t)/B_t$. The portfolio value process is then defined implicitly as the solution of the SDE

$$\begin{aligned} dX_t &= \alpha_t dS_t + q\alpha_t S_t dt + \beta_t dB_t \\ &= \alpha_t dS_t + q\alpha_t S_t dt + (X_t - \alpha_t S_t)r dt \\ &= rX_t dt + \alpha_t S_t \sigma (\theta dt + dw_t) \end{aligned} \quad (14)$$

where $\theta = (\mu - r + q)/\sigma$. This strategy is always self-financing since X_t is, by definition, the gains from trade process, while the value is $\alpha S + \beta B = X$.

Proof of Theorem (1) The key step is to put the “wealth equation” (14) into a more convenient form by **change of measure**. Define a measure $\mathbb{Q}$, the so-called *risk-neutral measure* on $(\Omega, \mathcal{F}_T)$ by the Radon–Nikodým derivative

$$\frac{d\mathbb{Q}}{d\mathbb{P}} = \exp\left(-\theta w_T - \frac{1}{2}\theta^2 T\right) \quad (15)$$

(The right-hand side has expectation 1, since $w_T \sim N(0, T)$.) Expectation with respect to $\mathbb{Q}$ will be denoted $\mathbb{E}_{\mathbb{Q}}$. By the *Girsanov theorem*, $\tilde{w} = w_t + \theta t$ is a $\mathbb{Q}$ -Brownian motion, so that from equation (1) the SDE satisfied by S_t under $\mathbb{Q}$ is

$$dS_t = (r - q)S_t dt + \sigma S_t d\tilde{w}_t \quad (16)$$

so that for $t < T$

$$\begin{aligned} S_T &= S_t \exp\left((r - q - \frac{1}{2}\sigma^2)(T - t) \right. \\ &\quad \left. + \sigma(\tilde{w}_T - \tilde{w}_t)\right) \end{aligned} \quad (17)$$

Applying the Itô formula and equation (14) we find that, with $\tilde{X}_t = e^{-rt} X_t$ and $\tilde{S}_t = e^{-rt} S_t$

$$d\tilde{X}_t = \alpha_t \tilde{S}_t \sigma d\tilde{w}_t \quad (18)$$

Thus $e^{-rt} X_t$ is a $\mathbb{Q}$ -local martingale under condition (12)(i). Let $h(S) = [S - K]^+$ and suppose there exists a replicating strategy, that is, a strategy (x, α, β) with value process X_t constructed as in equation (14) such that $X_T = h(S_T)$ a.s. Suppose also that α_t satisfies the stronger condition

$$\mathbb{E}_{\mathbb{Q}} \int_0^T \alpha_t^2 S_t^2 dt < \infty \quad (19)$$

Then $\tilde{X}_t$ is a $\mathbb{Q}$ -martingale, and hence for $t < T$

$$X_t = e^{-r(T-t)} \mathbb{E}_{\mathbb{Q}}[h(S_T) | \mathcal{F}_t] \quad (20)$$

and in particular

$$x = e^{-rT} \mathbb{E}_{\mathbb{Q}}[h(S_T)] \quad (21)$$

Now S_t is a **Markov process**, so the conditional expectation in equation (20) is a function of S_t , and indeed we see from equation (17) that S_T is a function of S_t and the increment $(\tilde{w}_T - \tilde{w}_t)$, which is independent of $\mathcal{F}_t$. Writing $(\tilde{w}_T - \tilde{w}_t) = Z\sqrt{T-t}$ where $Z \sim N(0, 1)$, the expectation is simply a one-dimensional integral with respect to the normal distribution. Hence, $X_t = C(t, S_t)$ where

$$\begin{aligned} C(t, S) &= \frac{e^{-r(T-t)}}{\sqrt{2\pi}} \int_{-\infty}^{\infty} h(S \exp((r - q - \sigma^2/2) \\ &\quad \times (T - t) - \sigma x \sqrt{T - t})) e^{-1/2x^2} dx \end{aligned} \quad (22)$$

Straightforward calculations show that this integral is equal to the closed-form expression in equation (6).

The argument so far shows that if there is a replicating strategy, the initial capital required must be $x = C(0, S_0)$ where C is defined by equation (22). It remains to identify the strategy (x, α, β) and to show that it is admissible. Let us temporarily take for granted the assertions of part (2) of the theorem; these will be proved in Theorem 3 below, where we also show that $(\partial C / \partial S)(t, S) = e^{-q(T-t)} N(d_1)$, so that in particular $0 < \partial C / \partial S < 1$.

The replicating strategy is $\mathcal{A} = (x, \alpha, \beta)$ defined by

$$\begin{aligned} x &= C(0, S_0), \quad \alpha_t = \frac{\partial C}{\partial S}(t, S_t) \\ \beta_t &= \frac{1}{rB_t} \left(\frac{\partial C}{\partial t} + \frac{1}{2}\sigma^2 S_t^2 \frac{\partial^2 C}{\partial S^2} - qS_t \frac{\partial C}{\partial S} \right) \end{aligned} \quad (23)$$

Indeed, using the PDE (9) we find that $X_t = \alpha_t S_t + \beta_t B_t = C(t, S_t)$, so that $\mathcal{A}$ is replicating and also $X_t \geq 0$, so that condition (12)(iii) is satisfied. From equation (17)

$$S_t^2 = S_0^2 \exp((2r - 2q - \sigma^2)t + 2\sigma \tilde{w}_t) \quad (24)$$

so that $\mathbb{E}_{\mathbb{Q}}[S_t^2] = \exp((2r - 2q + \sigma^2)t)$. Since $|e^{-r(T-t)} \partial C / \partial S| < 1$, this shows that $\mathbb{E}_{\mathbb{Q}} \int_0^T \alpha_t^2 S_t^2 dt < \infty$, that is, condition (19) is satisfied. Since β_t is, almost surely (a. s.), a continuous function of t it

satisfies equation (12)(ii). Thus $\mathcal{A}$ is admissible. The gain from trade in an interval $[s, t]$ is

$$\begin{aligned}
 & \int_s^t \alpha_u dS_u + \int_s^t q\alpha_u S_u du + \int_s^t \beta_u dB_u \\
 &= \int_s^t \frac{\partial C}{\partial S} dS + \int_s^t \left(\frac{\partial C}{\partial t} + \frac{1}{2} \sigma^2 S_t^2 \frac{\partial^2 C}{\partial S^2} \right) du \\
 &= \int_s^t dC \\
 &= C(t, S_t) - C(s, S_s)
 \end{aligned} \tag{25}$$

(We obtain the first equality from the definition of α, β , and it turns out to be just the Itô formula applied to the function C .) This confirms the self-financing property and completes the proof.

Finally, part (3) of the theorem follows from the model-free **put–call parity** relation $C - P = e^{-q(T-t)}S - e^{-r(T-t)}K$ and symmetry of the normal distribution: $N(-x) = 1 - N(x)$. $\square$

The replicating strategy derived above is known as **delta hedging**: the number of units of the risky asset held in the portfolio is equal to the Black–Scholes delta, $\Delta = \partial C / \partial S$.

So far, we have concentrated entirely on the hedging of call options. We conclude this section by showing that, with the class of trading strategies we have defined, there are no arbitrage opportunities in the Black–Scholes model.

Theorem 2 *There is no admissible trading strategy in a single asset and the zero-coupon bond that generates an arbitrage opportunity, in the Black–Scholes model.*

Proof Suppose X_t is the portfolio value process corresponding to an admissible trading strategy (x, α, β) . There is an arbitrage opportunity if $x = 0$ and, for some t , $X_t \geq 0$ a.s. and $\mathbb{P}[X_t > 0] > 0$, or equivalently $\mathbb{E}[X_t] > 0$. This is the $\mathbb{P}$ -expectation, but $\mathbb{E}[X_t] > 0 \Leftrightarrow \mathbb{E}_{\mathbb{Q}}[\tilde{X}_t] > 0$ since $\mathbb{P}$ and $\mathbb{Q}$ are equivalent measures and $e^{-rt} > 0$. From equation (18), $\tilde{X}_t$ is a $\mathbb{Q}$ -local martingale which, by the definition of admissibility, is bounded below by a constant $-L$. It follows that $\tilde{X}_t$ is a **supermartingale**, so if $x = 0$, then $\mathbb{E}_{\mathbb{Q}}[\tilde{X}_t] \leq 0$ for any t . So no arbitrage can arise from the strategy $(0, \alpha, \beta)$. $\square$

The Black–Scholes Partial Differential Equation

Theorem 3

1. The Black–Scholes PDE (9) with boundary condition (10) has a unique $C^{1,2}$ solution, given by equation (6).
2. The Black–Scholes “delta”, $\Delta(t, S)$, is given by

$$\Delta(t, S) = \frac{\partial}{\partial S} C(t, S) = e^{-q(T-t)} N(d_1) \tag{26}$$

Proof It can—with some pain—be directly checked that $C(t, S)$ defined by equation (6) does satisfy the Black–Scholes PDE (9), (10), and a further calculation (not quite as simple as it appears) gives the formula (26) for the Black–Scholes delta. It is, however, enlightening to take the original route of Black and Scholes and relate the equation (9) to a simpler equation, the *heat equation*. Note from the explicit expression (17) for the price process under the risk-neutral measure that, given the starting point S_t , there is a one-to-one relation between S_T and the Brownian increment $\tilde{w}_T - \tilde{w}_t$. We can therefore always express things interchangeably in “ S coordinates” or in “ $\tilde{w}$ coordinates”. In fact, we already made use of this in deriving the integral price expression (22). Here we proceed as follows.

For fixed parameters S_0, r, q, σ , define the functions $\phi : \mathbb{R}^+ \times \mathbb{R} \rightarrow \mathbb{R}^+$ and $u : [0, T] \times \mathbb{R} \rightarrow \mathbb{R}^+$ by

$$\phi(t, x) = S_0 \exp \left(\left(r - q - \frac{1}{2} \sigma^2 \right) t + \sigma x \right) \tag{27}$$

and

$$u(t, x) = C(t, \phi(t, x)) \tag{28}$$

Note that the inverse function $\psi(t, s) = \phi^{-1}(t, s)$ (i.e., the solution for x of the equation $s = \phi(t, x)$) is

$$\psi(t, s) = \frac{1}{\sigma} \left(\log \left(\frac{s}{S_0} \right) - \left(r - q - \frac{1}{2} \sigma^2 \right) t \right) \tag{29}$$

A direct calculation shows that C satisfies equation (9) if and only if u satisfies the heat equation

$$\frac{\partial u}{\partial t} + \frac{1}{2} \frac{\partial^2 u}{\partial x^2} - r u = 0 \tag{30}$$

If W_t is Brownian motion on some probability space and u is a $C^{1,2}$ function, then an application of the Itô formula shows that

$$d(e^{-rt}u(t, W_t)) = e^{-rt} \left(\frac{\partial u}{\partial t} + \frac{1}{2} \frac{\partial^2 u}{\partial x^2} - ru \right) dt + e^{-rt} \frac{\partial u}{\partial x} dW_t \quad (31)$$

If u satisfies equation (30) with boundary condition $u(T, x) = g(x)$ and

$$\mathbb{E} \int_0^T \left(\frac{\partial u}{\partial x}(t, W_t) \right)^2 dt < \infty \quad (32)$$

then the process $t \mapsto e^{-rt}u(t, W_t)$ is a martingale so that, with $\mathbb{E}_{t,x}$ denoting the conditional expectation given $W_t = x$,

$$\begin{aligned} e^{-rt}u(t, x) &= \mathbb{E}_{t,x}[e^{-rT}u(T, W_T)] \\ &= \mathbb{E}_{t,x}[e^{-rT}g(W_T)] \end{aligned} \quad (33)$$

Since $W_T \sim N(x, T - t)$, this shows that u is given by

$$u(t, x) = \frac{e^{-r(T-t)}}{\sqrt{2\pi(T-t)}} \int_{-\infty}^{\infty} g(y) e^{-\frac{(y-x)^2}{2(T-t)}} dy \quad (34)$$

A sufficient condition for equation (32) is

$$\frac{1}{\sqrt{2\pi T}} \int_{-\infty}^{\infty} g^2(y) e^{-y^2/2T} dy < \infty \quad (35)$$

In our case, the boundary condition is $g(x) = [\phi(t, x) - K]^+ < \phi(t, x)$ and this condition is easily checked. Hence, equation (30) with this boundary condition has unique $C^{1,2}$ solution (34), implying that the inverse function $C(t, S) = u(t, \psi(t, S))$ given by

equation (22) is the unique $C^{1,2}$, solution of equation (9) as claimed. $\square$

Hedge Parameters

Bringing in all the parameters, the Black–Scholes formula (6) is a six-parameter function $C(t, S) = C(\tau, S, K, r, q, \sigma)$, where $\tau = T - t$ is the time to maturity. For risk-management purposes, it is important to know the sensitivities of the option value to changes in the parameters. The conventional hedge parameters or “greeks” are given in Table 1. There are slight notational problems in that “vega” is not the name of a Greek letter (here we have used upper-case upsilon, but this is not necessarily a conventional choice) and upper-case rho coincides with Latin P, so this parameter is usually written ρ , risking confusion with correlation parameters. The expressions in the right-hand column are readily obtained from the sensitivity parameters (42) and (43) of the “universal” Black Formula introduced below.

Delta is, of course, the Black–Scholes hedge ratio. Gamma measures the convexity of C and is at its maximum when the option is close to being at the money. Since gamma is the rate of change of delta, frequent rebalancing of the hedge portfolio will be required in areas of high gamma. Theta is defined as $-\partial C/\partial \tau$ and is generally negative (as can be seen from the table, it is always negative for a call option on an asset with no dividends). It represents the “time decay” in the option value as the maturity time is reduced, that is, real time advances. As regards rho, it is not immediately obvious, without doing the calculation, what its sign will be: on one hand, increasing r increases the forward price, pushing a call option further into the money, while on the other hand increased r implies heavier discounting, reducing option value. As can be seen from the table,

Table 1 Black–Scholes risk parameters

Delta	Δ	$\frac{\partial C}{\partial S}$	$e^{-q\tau} N(d_1)$
Gamma	Γ	$\frac{\partial^2 C}{\partial S^2}$	$\frac{e^{-q\tau} N'(d_1)}{S\sigma\sqrt{\tau}}$
Theta	Θ	$-\frac{\partial C}{\partial \tau}$	$-\frac{e^{-q\tau} S N'(d_1) \sigma}{2\sqrt{\tau}} + q e^{-q\tau} S N(d_1) - r K e^{-r\tau} N(d_2)$
Rho	P	$\frac{\partial C}{\partial r}$	$K \tau e^{-r\tau} N(d_2)$
Vega	Υ	$\frac{\partial C}{\partial \sigma}$	$e^{-q\tau} S \sqrt{\tau} N'(d_1)$

the first effect wins: rho is always positive. Vega is in some ways the most important parameter, since a key risk in managing books of traded options is “vega risk”, and in Black–Scholes this is completely “outside the model”. Bringing it back inside the model is the subject of **stochastic volatility**.

An extensive discussion of the risk parameters and their uses can be found in Hull [6].

The Black “Forward” Option Formula

The six-parameter representation $\mathcal{C}(\tau, S, K, r, q, \sigma)$ is not the best parameterization of Black–Scholes. For the asset S_t with dividend yield q , the *forward price* at time t for delivery at time T is $F(t, T) = S_t e^{(r-q)(T-t)}$ (this is a model-free result, not related to the Black–Scholes model). We can trivially re-express the price formula (6) as

$$C(t, S_t) = B(t, T)(F(t, T)N(d_1) - KN(d_2)) \quad (36)$$

with

$$d_1 = \frac{\log(F(t, T)/K) + \frac{1}{2}\sigma^2(T-t)}{\sigma\sqrt{T-t}} \\ d_2 = d_1 - \sigma\sqrt{T-t} \quad (37)$$

where $B(t, T) = e^{-r(T-t)}$ is the zero-coupon bond value or “discount factor” from T to t . There is, however, far more to this than just a change of notation. First, the continuously compounding rate r is not market data. The market data at time t is the set of discount factors $B(t, t')$ for $t' > t$. We see from equation (36) that “ r ” plays two distinct roles in Black–Scholes: it appears in the computation of the forward price F and the discount factor B . But both of these are more fundamental than r itself and are, in fact, market data which, as equation (36) shows, can be used directly. A further advantage is that the exact mechanism of dividend payment is not important, as long as there is an unambiguously defined forward price.

Formula (36) is known as the *Black formula* and is the most useful version of Black–Scholes, being widely applied in connection with FX (**foreign exchange**) and **interest-rate options** as well as dividend-paying equities. Fundamentally, it relates to a price model in which the price is expressed in the

risk-neutral measure as $S_t = F(0, t)M_t$ where M_t is the exponential martingale

$$M_t = \exp\left(\sigma\check{w}_t - \frac{1}{2}\sigma^2 t\right) \quad (38)$$

which is equivalent to equation (17). This model accords with the general fact that, in a world of deterministic interest rates, the forward price is the expected price in the risk-neutral measure, that is, the ratio $S_t/F(0, t)$ is a positive martingale with expectation 1. The exponential martingale (38) is the simplest continuous-path process with these properties.

A Universal Black Formula

The parameterization of Black–Scholes can be further compressed as follows. First, note that σ and $\tau = (T - t)$ do not appear separately, but only in the combination $a = \sigma\sqrt{T - t}$, where a^2 is sometimes known as the *operational time*. Next, define the “moneyness” m as $m(t, T) = K/F(t, T)$, and define

$$d(a, m) = \frac{a}{2} - \frac{\log m}{a} \quad (39)$$

(so that $d_1 = d(\sigma\sqrt{T - t}, K/F(t, T))$). Then the Black formula (36) becomes

$$C = BF f(a, m) \quad (40)$$

where

$$f(a, m) = N(d(a, m)) - mN(d(a, m) - a) \quad (41)$$

Now BF is the price of a zero-strike call, or equivalently the price to be paid at time t for delivery of the asset at time T . Formula (40) says that the price of the K -strike call is the (model-free) price of the zero-strike call modified by a factor f that depends only on the moneyness and operational time. We call f the *universal Black–Scholes function*, and a graph of it is shown in Figure 1. With $N' = dN/dx$ and $d = d(a, m)$ we find that $mN'(d - a) = N'(d)$ and hence obtain the following very simple expressions for the first-order derivatives:

$$\frac{\partial f}{\partial a}(a, m) = N'(d) \quad (42)$$

$$\frac{\partial f}{\partial m}(a, m) = -N(d - a) \quad (43)$$

In particular, $\partial f/\partial a > 0$ and $\partial f/\partial m < 0$ for all a, m .

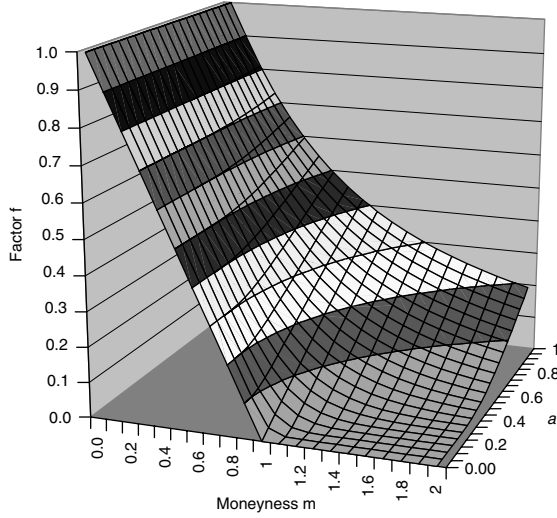

Figure 1 The universal Black–Scholes function

This minimal parameterization of Black–Scholes is used in studies of stochastic volatility; see, for example, **Gatheral** [5].

Implied Volatility and Market Trading

So far, our discussion has been entirely within the Black–Scholes model. What happens if we attempt to use Black–Scholes delta hedging in real market trading? This question has been considered by several authors, including El Karoui *et al.* [3] and Fouque *et al.* [4], though neither of these discusses the effect of jumps in the price process.

In the universal price formula (40), the parameters B, F, m are market data, so we can regard the formula as a mapping $a \mapsto p = BFf(a, m)$ from a to price $p \in [B[F - K]^+, BF)$. In a traded options market, p is market data (but must lie in the stated interval, else there is a static arbitrage opportunity). In view of equation (42), $f(a, m)$ is strictly increasing in a and hence there is a unique value $a = \hat{a}(p)$ such that $p = BFf(\hat{a}(p), m)$. The *implied volatility* is $\hat{\sigma}(p) = \hat{a}(p)/\sqrt{T - t}$. If the underlying price process S_t actually were geometric Brownian motion (1), then $\hat{\sigma}$ would be the same, and equal to the volatility σ , for call options of all strikes and maturities. Of course, this is never the case in practice—see [5] for

a discussion. Here, we restrict ourselves to examining what happens if we naïvely apply the Black–Scholes delta-hedge when in reality the underlying process is *not* geometric Brownian motion, taking $q = 0$ for simplicity. Specifically, we assume that the “true” price model, under measure $\mathbb{P}$, is

$$S_t = S_0 + \int_0^t \eta_t S_{t-} dt + \int_0^t \kappa_t S_{t-} dW_t + \int_{[0,t] \times \mathbb{R}} S_{t-} v_t(z) \mu(dt, dz) \quad (44)$$

where μ is a finite-activity *Poisson random measure*, so that there is a finite measure ν on $\mathbb{R}$ such that $\mu([0, t] \times A) - \nu(A)t \equiv (\mu - \pi)([0, t] \times A)$ is a martingale for each $A \in \mathcal{B}(\mathbb{R})$. η, κ, v are predictable processes. Assume that η, κ and v are such that the solution to the SDE (44) is well defined and, moreover, that $v_t(z) > -1$ so $S_t > 0$ almost surely. This is a very general model including path-dependent coefficients, stochastic volatility, and jumps. Readers unfamiliar with jump-diffusion models can set $\mu = \nu = \pi = 0$ below, and refer to the last paragraph of this section for comments on the effect of jumps.

Consider the scenario of selling at time 0 a European call option at implied volatility $\hat{\sigma}$, that is, for the price $p = C(T, S_0, K, r, \hat{\sigma})$ and then following a Black–Scholes delta-hedging trading strategy based on constant volatility $\hat{\sigma}$ until the option expires at time T . As usual, we shall denote $C(t, s) = C(T - t, s, K, r, \hat{\sigma})$, so that the hedge portfolio, with value process X_t , is constructed by holding $\alpha_t := \partial_S C(t, S_{t-})$ units of the risky asset S , and the remainder $\beta_t := \frac{1}{B_t}(X_{t-} - \alpha_t S_{t-})$ units in the riskless asset B (a unit notional zero-coupon bond). This portfolio, initially funded by the option sale (so $X_0 = p$), defines a self-financing trading strategy. Hence, the portfolio value process X satisfies the SDE

$$\begin{aligned} X_t = p &+ \int_0^t \partial_S C(u, S_{u-}) \eta_u S_{u-} du \\ &+ \int_0^t \partial_S C(u, S_{u-}) \kappa_u S_{u-} dW_u \\ &+ \int_{[0,t] \times \mathbb{R}} \partial_S C(u, S_{u-}) S_{u-} v_u(z) \mu(du, dz) \\ &+ \int_0^t (X_u - \partial_S C(u, S_{u-}) S_u) r du \end{aligned} \quad (45)$$

Now define $Y_t = C(t, S_t)$, so that, in particular, $Y_0 = p$. Applying the Itô formula (Lemma 4.4.6 of [1]) gives

$$\begin{aligned} Y_t &= p + \int_0^t \partial_t C(u, S_{u-}) du \\ &\quad + \int_0^t \partial_S C(u, S_{u-}) \eta_u S_{u-} du \\ &\quad + \int_0^t \partial_S C(u, S_{u-}) \kappa_u S_{u-} dW_u \\ &\quad + \frac{1}{2} \int_0^t \partial_{SS}^2 C(u, S_{u-}) \kappa_u^2 S_{u-}^2 du \\ &\quad + \int_{[0,t] \times \mathbb{R}} (C(u, S_{u-}(1 + v_u(z))) \\ &\quad - C(u, S_{u-})) \mu(dt, dz) \end{aligned} \quad (46)$$

Thus the ‘hedging error’ process defined by $Z_t := X_t - Y_t$ satisfies the SDE

$$\begin{aligned} Z_t &= \int_0^t r X_u du - \int_0^t (r S_{u-} \partial_S C(u, S_{u-}) \\ &\quad + \partial_t C(u, S_{u-}) + \frac{1}{2} \kappa_u^2 S_{u-}^2 \partial_{SS}^2 C(u, S_{u-})) du \\ &\quad - \int_{[0,t] \times \mathbb{R}} (C(u, S_{u-}(1 + v_u(z))) - C(u, S_{u-}) \\ &\quad - \partial_S C(u, S_{u-}) S_{u-} v_u(z)) \mu(du, dz) \\ &= \int_0^t r Z_u du + \frac{1}{2} \int_0^t \Gamma(u, S_{u-}) S_{u-}^2 (\hat{\sigma}^2 - \kappa_u^2) du \\ &\quad - \int_{[0,t] \times \mathbb{R}} (C(u, S_{u-}(1 + v_u(z))) \\ &\quad - C(u, S_{u-}) - \partial_S C(u, S_{u-}) S_{u-} v_u(z)) \mu(du, dz) \end{aligned} \quad (47)$$

where $\Gamma(t, S_t) = \partial_{SS}^2 C(t, S_t)$, and the last equality follows from the Black–Scholes PDE. Therefore, the final difference between the hedging strategy and the required option payout is given by

$$\begin{aligned} Z_T &= X_T - [S_T - K]^+ \\ &= \frac{1}{2} \int_0^T e^{r(T-t)} S_{t-}^2 \Gamma(t, S_{t-}) (\hat{\sigma}^2 - \kappa_t^2) dt \end{aligned}$$

$$\begin{aligned} &- \int_{[0,T] \times \mathbb{R}} e^{r(T-t)} \left(\int_0^1 \int_0^\epsilon \Gamma(t, S_{t-}(1 + \epsilon' v_t(z))) \right. \\ &\quad \times v_t^2(z) S_{u-}^2 d\epsilon' d\epsilon \Big) \pi(dt, dz) - M_T \end{aligned} \quad (48)$$

where M_T is the terminal value of the martingale

$$\begin{aligned} M_t &= \int_{[0,T] \times \mathbb{R}} e^{r(T-t)} \left(\int_0^1 \int_0^\epsilon \Gamma(t, S_{t-}(1 + \epsilon' v_t(z))) \right. \\ &\quad \times v_t^2(z) S_{u-}^2 d\epsilon' d\epsilon \Big) (\mu - \pi)(dt, dz) \end{aligned} \quad (49)$$

Equation (48) is a key formula, as it shows that successful hedging is quite possible even under significant model error. Without some ‘robustness’ property of this kind, it is hard to imagine that the derivatives industry could exist at all, since hedging under realistic conditions would be impossible.

Consider first the case $\mu \equiv 0$, where S_t has continuous sample paths and the last two terms in equation (48) vanish. Then, successful hedging depends entirely on the relationship between the implied volatility $\hat{\sigma}$ and the true ‘local volatility’ κ_t . Note from Table 1 that $\Gamma_t > 0$. If we, as option writers, are lucky and $\hat{\sigma}^2 \geq \kappa_t^2$ a.s. for all t , then the hedging strategy makes a profit *with probability 1* even though the true price model is substantially different from the assumed model as in equation (1). On the other hand, if we underestimate the volatility, we will consistently make a loss. The magnitude of the profit or loss depends on the option convexity Γ . If Γ is small, then hedging error is small even if the volatility has been grossly misestimated.

For the option writer, jumps in either direction are unambiguously bad news. Since C is convex, $\Delta C > (\partial C / \partial S) \Delta S$, so the last term in equation (47) is monotone decreasing: the hedge profit takes a hit every time there is a jump, either upward or downward, in the underlying price. However, there is some recourse: in equation (48), M_T has expectation 0 while the penultimate term is negative. By increasing $\hat{\sigma}$ we increase $\mathbb{E}[Z_T]$, so we could arrive at a situation where $\mathbb{E}[Z_T] > 0$, although in this case there is no possibility of *with probability 1* profit because of the martingale term. All of this reinforces the trader’s intuition that one can offset additional hedge costs by charging more upfront (i.e.,

increasing $\hat{\sigma}$) and hedging at the higher level of implied volatility.

End Notes

^aA two-parameter function is $C^{1,2}$ if it is once (twice) continuously differentiable in the first (second) argument.

Exchange Options

Definition and Examples

A European exchange option is a contract that gives the buyer the right to exchange two (possibly dividend-paying) assets A and B at a fixed expiration time T , say, to receive A and deliver (or pay) B ; thus, the option payoff is

$$(A_T - B_T)^+ := \max(A_T - B_T, 0) \quad (1)$$

(American and Bermudan exchange options are complicated by early optimal exercise and not discussed here.) An ordinary (European) call or put on an asset struck at K can be viewed, as in [9], as an option to exchange the asset with the T -maturity zero-coupon bond of principal K . More generally, a call or put on an s -maturity forward contract ($s \geq T$) on a zero-dividend asset is equivalent to an option to exchange the asset at time T with an s -maturity zero-coupon bond. Options to exchange two stocks or commodities provide good hypothetical examples but are not prevalent in the market place.

Exchange options are related to spread options with time- T payoffs of the form $(X - Y)^+$, given two prescribed time- T observables X and Y . A common structure is a CMS spread option, with X and Y , say, the 20-year and the 2-year spot swap rates at time T . A spread option can be viewed as an exchange option when there exist (or can be replicated) two zero-dividend assets A and B such that $A_T = X$ and $B_T = Y$. In the CMS case, A and B can be taken as the coupon cash flows of two CMS bonds or swaps. In practice, exchange options on dividend-paying assets are reduced to the zero-dividend case in a similar way.

Interest-rate swaptions, including caplets and floorlets as one-period special cases, can be viewed both as ordinary call or put options struck at par on coupon bonds and more directly as options to exchange the fixed and floating cash flow legs of a swap. The latter is the standard as it imposes the classical assumption of a lognormal ratio A_T/B_T on the forward swap rate (a swap-curve concept) rather than on the forward coupon bond price.

An exchange option is related to its reverse by parity: $(Y - X)^+ = (X - Y)^+ + Y - X$. (Hence, an

American option to exchange two fixed zero-dividend assets is not exercised early.)

Pricing and Hedging Approaches

The exchange option is a special case of a *path-independent* contingent claim with payoff being a *homogeneous function* of the underlying asset prices at expiration. It is governed by the same general theory (see **Option Pricing: General Principles**). One makes sure that the underlying assets are arbitrage free, which implies that there are no free lunches in a strong sense. If the payoff can be attained by a sufficiently regular self-financing trading strategy (SFTS) (e.g., a bounded number of shares or “deltas”), then the law of one price holds and the option price at each time is defined as the value of the self-financing portfolio. Otherwise, arbitrage-free pricing is not unique. We do not discuss this case, but only mention that one approach then chooses a linear pricing kernel (e.g., the minimal measure) among the many then available and another is nonlinear based on expected utility maximization.

Payoff replication by an SFTS is a question of predictable representation. As the payoff in this case is a path-independent function of the underliers, it seems natural that the option price as well as deltas be functions of time and the underliers at that time. This has been the traditional Markovian approach, beginning with Black and Scholes [1] and immediate extension by Merton [9] (see **Black–Scholes Formula**). Their simple choice of a geometric Brownian motion for the underlying asset in [1] and more generally of a deterministic-volatility forward price process in [9] meant that the underlying SDE and the associated PDE had constant coefficients (in log-state). Itô’s formula was applied to construct a riskless hedge, with the deltas (hedge ratios) simply given by partial derivatives of the unique solution to the PDE.

Black and Scholes constructed an SFTS for a call option struck at K by dynamically rebalancing long positions on the underlying asset A financed by shorting the riskless money market asset $B^* = (e^{rt})$, post an initial investment equal to the option price. Merton’s extension to stochastic interest rate r treated the call as an option C to exchange the asset A with the T -maturity zero-coupon bond B of principal K . The Black–Scholes model corresponded to a

deterministic bond price $B_t = e^{-r(T-t)}K$, but now, in general, B had infinite variation. The former's simplicity was nonetheless recaptured by exploiting the homogeneous symmetry of the option payoff to reduce dimensionality by 1—in effect, a projective transformation that hedged the forward option contract $F := C/B$ with trades in the forward asset $X := A/B$. The relevant volatility was accordingly the forward price volatility. An SFTS in the two assets and Itô's formula led to a PDE for the homogeneous option price function $C(t, A, B)$ and an equivalent PDE for the forward option price function $F(t, X)$.

Margrabe [8] extended the theory in [9] to an option to exchange any two correlated assets assuming constant volatilities (*see Margrabe Formula*). He observed akin to [9] that the self-financing equation with $\partial C/\partial A$ and $\partial C/\partial B$ as deltas is, by Itô's formula, equivalent to $C(t, A, B)$ satisfying a PDE with no first-order terms in A, B . Choosing C as the homogenized Black–Scholes function, it followed by Euler's formula for homogeneous functions that $\partial C/\partial A$ and $\partial C/\partial B$ in fact formed an SFTS. The result demonstrated that (in this case) the exchange option is replicated by dynamically going long in A and short in B , with no trades in any other asset. (This fails in general, e.g., a bond exchange option in a $k \geq 3$ factor non-Gaussian short-rate model.) “*Taking asset two as numéraire*,” Margrabe [8] also presented (acknowledging Stephen Ross) a key financial invariance argument as a heuristic alternative to the PDE algebraic proof of [9], reducing to a call on A/B struck at 1 in the Black–Scholes model with zero interest rate.

Martingale theory leads to a conceptual as well as computationally practical representation of solutions to the PDEs that describe option prices as a conditional expectation of terminal payoff. Harrison and Kreps [5] and Harrison and Pliska [6] developed, in related papers, an equivalent martingale measure framework that not only made this fruitful representation of the option price available but also laid a more general and probabilistic formulation of the notion of a dynamic hedge, or its mirror image, a replicating SFTS (*see Risk-neutral Pricing*). Their arbitrage-free semimartingale approach does permit path dependency, yet accommodates Markovian SDE/PDE models even better. They took the money market asset B^* as a tradable entering any hedge, giving it a general stochastic form

$B_t^* = e^{\int_0^t r_s ds}$ for discounting payoffs before expectation. In concert with Black–Scholes but in contrast to Merton and Margrabe, the finite variation asset B^* was their exclusive choice of numéraire.

With the advent of the forward measure sometime later (*see Forward and Swap Measures*), it was evident that Merton's choice of an infinite variation zero-coupon bond B as the financing hedge instrument fitted equivalent martingale measure theory perfectly well, and it led to quicker derivations of concrete pricing formulae than B^* , as discounting is conveniently performed outside the expectation [4, 7]. Another useful numéraire was the one by Neuberger [10] to price interest-rate swaptions. Viewed as an option to exchange the fixed and floating swap cash flows, the assets' ratio A/B represents the forward swap rate here. The assumption in [10] that the ratio has deterministic volatility yielded a model that has since served as industry standard to quote swaption-implied volatilities (*see Swap Market Models*). Here, it is noteworthy that the ratio A/B has deterministic volatility but A and B themselves decidedly do not. In time, El-Karoui *et al.* [4] showed that one can basically change numéraire to any asset B and associate with it an equivalent measure under which A/B is a martingale for every other asset A (*see Change of Numéraire*).

Today, option pricing and hedging theory has advanced farther and in many directions. Especially relevant to our discussion of exchange options is the principle of numéraire invariance and arbitrage-free modeling. For in-depth studies of these and related topics, we refer the reader to [3] and [2], among other excellent books. Our approach is to concentrate on the modeling in “projective coordinate” $X := A/B$, and impose for the most part conditions that are invariant under the transformation $X \mapsto 1/X$.

The Deterministic-volatility and Exponential-Poisson Models

The option to exchange two assets with a *deterministic volatility* $\sigma(t)$ of the asset price ratio $X = A/B$ is celebrated as the simplest nontrivial example in option pricing theory. Its classical Black–Scholes/Merton option price function and explicit representation of the “deltas” (“hedge ratios”) illustrate the principles that underline options in many assets with arbitrary homogeneous payoffs and more

general dynamics. There is another concrete albeit less known example with simple jumps in X involving the Poisson rather than the normal distribution. The pattern is similar, with the main difference being that the deltas are the partial differences rather than the partial derivatives of the option price function.

We fix, throughout, a stochastic basis $(\Omega, (\mathcal{F}_t), \mathcal{F}, \mathbb{P})$ with time horizon $t \in [0, T]$, $T > 0$. In this section, we fix two *zero-dividend* assets with price processes $A = (A_t)$ and $B = (B_t)$.

The Exchange Option Price Process

When A and B are semimartingales, we call a pair (δ^A, δ^B) of (locally) bounded predictable processes a (locally) *bounded SFTS* (see, more generally, the section Self-financing Trading Strategies) if $C = C_0 + \int \delta^A dA + \int \delta^B dB$, where

$$C = \delta^A A + \delta^B B \quad (2)$$

Clearly, C is then a semimartingale, $\Delta C = \delta^A \Delta A + \delta^B \Delta B$, and hence $C_- = \delta^A A_- + \delta^B B_-$.

The differential form of the self-financing equation is often handy:

$$dC = \delta^A dA + \delta^B dB \quad (3)$$

SFTSs form a linear space. If there exists a unique *bounded SFTS* (δ^A, δ^B) such that

$$C_T = (A_T - B_T)^+ \quad (4)$$

then it is justified to call C the *exchange option price process* and δ^A and δ^B the *deltas*.

Assume now that the semimartingales A and B are positive and have positive left limits.

The numéraire invariance principle (see the section Numéraire Invariance and more comprehensively the section The Invariance Principle) states that if (δ^A, δ^B) is a locally bounded SFTS, then $C = \delta^A A + \delta^B B$ satisfies $d\left(\frac{C}{B}\right) = \delta^A d\left(\frac{A}{B}\right)$ (similarly by symmetry with A as numéraire). This is useful for uniqueness. Numéraire invariance also states the converse: if C is a semimartingale and δ^A a locally bounded predictable process such that $d\left(\frac{C}{B}\right) = \delta^A d\left(\frac{A}{B}\right)$, then (δ^A, δ^B) is an SFTS and equations (2) and (3) hold, where $\delta^B = \frac{C_-}{B_-} - \delta^A \frac{A_-}{B_-}$.

This reduces existence to finding an F_0 and δ^A such that

$$\left(\frac{A_T}{B_T} - 1\right)^+ = F_0 + \int_0^T \delta_t^A d\left(\frac{A_t}{B_t}\right) \quad (5)$$

The exchange option price process is then the semimartingale $C = B \left(F_0 + \int \delta^A d\left(\frac{A}{B}\right) \right)$.

Numéraire invariance in effect reduces general option pricing and hedging to a market where one of the asset price processes equals 1 identically. The remaining task is to find the above “projective” predictable representation of the ratio payoff against the ratio process.

Deterministic-volatility Exchange Option Model

Let $\sigma(t) > 0$ be a continuous positive function. Define the *Black–Scholes/Merton projective option price function*

$$f(t, x) := x\delta_A(t, x) + \delta_B(t, x) \quad (6)$$

for $t \leq T$, $x > 0$, where $\delta_A(T, x) := 1_{x>1}$, $\delta_B(T, x) := -1_{x>1}$, and for $t < T$,

$$\begin{aligned} \delta_A(t, x) &:= N\left(\frac{\log x}{\sqrt{v_t}} + \frac{\sqrt{v_t}}{2}\right), \\ \delta_B(t, x) &:= -N\left(\frac{\log x}{\sqrt{v_t}} - \frac{\sqrt{v_t}}{2}\right) \end{aligned} \quad (7)$$

where $v_t := \int_t^T \sigma^2(s) ds$ and $N(\cdot)$ is the normal distribution function. The function $f(t, x)$ is continuous, and on $t < T$ is C^1 in t and analytic in x . In addition, $-1 \leq \delta_B \leq 0 \leq \delta_A \leq 1$, and

$$f(T, x) = (x - 1)^+, \quad \frac{\partial f}{\partial x}(t, x) = \delta_A(t, x) \quad (8)$$

As is well known and seen in the sections Deterministic-volatility Model Uniqueness and Projective Continuous SDE SFTS, the function $f(t, x)$ is the unique $C^{1,2}$ (on $t < T$) solution with bounded partial derivative $\frac{\partial f}{\partial x}(t, x)$ subject to $f(T, x) = (x - 1)^+$ of the PDE

$$\frac{\partial f}{\partial t}(t, x) + \frac{1}{2}\sigma^2(t)x^2 \frac{\partial^2 f}{\partial x^2}(t, x) = 0 \quad (9)$$

4 Exchange Options

Assume now $A = BX$ for some positive continuous semimartingale $X > 0$ satisfying

$$d[\log X]_t = \sigma^2(t)dt, \quad (A = BX) \quad (10)$$

Under this assumption, one traditionally defines the exchange option price process C by

$$C := BF, \quad F = (F_t), \quad F_t := f(t, X_t) \quad (11)$$

Clearly, $C_T = (A_T - B_T)^+$. The definition is justified using the continuous semimartingales

$$\begin{aligned} \delta_t^A &:= \delta_A(t, X_t) = \frac{\partial f}{\partial x}(t, X_t), \\ \delta_t^B &:= \delta_B(t, X_t) = F_t - \delta_t^A X_t \end{aligned} \quad (12)$$

Clearly, $C = \delta^A A + \delta^B B$, and the deltas are bounded: $0 \leq \delta^A \leq 1$ and $-1 \leq \delta^B \leq 0$. Since $f(t, x)$ satisfies the PDE (9) (as directly verified) and $\frac{\partial f}{\partial x}(t, X_t) = \delta_t^A$, by Itô's formula, the continuous semimartingale $F := (f(t, X_t))$ satisfies the predictable representation

$$dF = \delta^A dX \quad (13)$$

If, at this stage, we assume that B is a semimartingale, then A and C are semimartingales too, and by the invariance principle discussed next, $dC = \delta^A dA + \delta^B dB$ and (δ^A, δ^B) is a bounded SFTS.

Numéraire Invariance

Let X and F be two semimartingales and δ^A be a locally bounded predictable process such that $dF = \delta^A dX$. Set $\delta^B = F - \delta^A X$. Clearly $\delta^B = F_- - \delta^A X_-$ since $\Delta F = \delta^A \Delta X$. Let B be any semimartingale. Set $A = BX$, $C = BF$. Clearly $C = \delta^A A + \delta^B B$. We claim $dC = \delta^A dA + \delta^B dB$, so (δ^A, δ^B) is an SFTS.

Indeed, this follows by applying Itô's product rule to BF , then substituting $dF = \delta^A dX$ and $F_- = \delta^B + \delta^A X_-$, followed by Itô's product rule on BX :

$$\begin{aligned} dC &= d(BF) = B_- dF + F_- dB + d[B, F] \\ &= B_- \delta^A dX + (\delta^B + \delta^A X_-)dB + \delta^A d[B, X] \\ &= \delta^A d(BX) + \delta^B dB = \delta^A dA + \delta^B dB \end{aligned} \quad (14)$$

Conversely, if A and B are semimartingales with $B, B_- > 0$ and (δ^A, δ^B) is an SFTS, then

$d\left(\frac{C}{B}\right) = \delta^A d\left(\frac{A}{B}\right)$, where $C = \delta^A A + \delta^B B$. (See the section The Invariance Principle for a more lucid treatment.)

Exponential-Poisson Exchange Option Model

Assume that the two zero-dividend asset price processes A and B satisfy $A = BX$, where X is a semimartingale satisfying

$$X_t = X_0 e^{\beta P_t - (\beta - 1)\lambda t} \quad (15)$$

for some constants $\beta \neq 0$, $\lambda > 0$ and semimartingale P such that $[P] = P$ and $P_0 = 0$ (Thus, $P_t = \sum_{s \leq t} 1_{\Delta P_s \neq 0}$). Define the projective option price function $f(t, x)$, $x > 0$ by

$$\begin{aligned} f(t, x) &:= \sum_{n=0}^{\infty} (x e^{\beta n - (\beta - 1)\lambda(T-t)} - 1)^+ \\ &\quad \times \frac{\lambda^n}{n!} (T - t)^n e^{-\lambda(T-t)} \end{aligned} \quad (16)$$

and exchange option price process by

$$C := BF, \quad F = (F_t), \quad F_t := f(t, X_t) \quad (17)$$

Clearly $f(T, x) = (x - 1)^+$ and $C_T = (A_T - B_T)^+$. One has the predictable representation

$$dF = \delta^A dX \quad (18)$$

as shown shortly, where

$$\delta_t^A := \delta_A(t, X_{t-}), \quad \delta_A(t, x) := \frac{f(t, e^\beta x) - f(t, x)}{(e^\beta - 1)x} \quad (19)$$

Thus by numéraire invariance, (δ^A, δ^B) is an SFTS if A and B are semimartingales, where

$$\delta^B := F - \delta^A X = F_- - \delta^A X_- \quad (20)$$

Moreover, it is bounded. Indeed, since $|(e^\beta y - 1)^+ - (y - 1)^+| \leq |e^\beta - 1|y$ for any $y > 0$,

$$\begin{aligned} 0 \leq \delta_A(t, x) &\leq \sum_{n=0}^{\infty} e^{\beta n - (\beta - 1)\lambda(T-t)} \\ &\quad \times \frac{\lambda^n}{n!} (T - t)^n e^{-\lambda(T-t)} = 1 \end{aligned} \quad (21)$$

Hence, $0 \leq \delta^A \leq 1$. Similarly, $-1 \leq \delta^B \leq 0$.

We note that $f(t, x)$ is *not* C^1 in x (though convex, absolutely continuous, and piecewise analytic in x). We also caution that this model is arbitrage free only when $\mathbb{P}\{P_t = n\} > 0$ for all $t > 0$ and $n \in \mathbb{N}$, for example, when P is a Poisson process under an equivalent measure.

Derivation of the Predictable Representation

To show $dF = \delta^A dX$ (equation (18)), we first note that $[P]^c = 0$ since $[P] = P$; hence, $(\Delta P)^2 = \Delta P$ and $P_t = [P]_t = \sum_{s \leq t} \Delta P_s$. If $v(p)$, $p \in \mathbb{R}$, is any function, then clearly $V = (v(P_t))$ is a semimartingale and we have

$$\begin{aligned} \Delta V_t &= v(P_t) - v(P_{t-}) = (v(P_t) - v(P_{t-}))\Delta P_t \\ &= (v(P_{t-} + 1) - v(P_{t-}))\Delta P_t \end{aligned} \quad (22)$$

Hence, as V is clearly the sum of its jumps,

$$\begin{aligned} V_t - v(0) &= \sum_{s \leq t} \Delta V_s \\ &= \sum_{s \leq t} (v(P_{s-} + 1) - v(P_{s-}))\Delta P_s \\ &= \int_0^t (v(P_{s-} + 1) - v(P_{s-}))dP_s \end{aligned} \quad (23)$$

Likewise, $(u(t, P_t))$ is a semimartingale for any C^1 in t function $u(t, p)$, $p \in \mathbb{R}$, and one has

$$\begin{aligned} du(t, P_t) &= \frac{\partial u}{\partial t}(t, P_{t-})dt + (u(t, P_{t-} + 1) \\ &\quad - u(t, P_{t-}))dP_t \end{aligned} \quad (24)$$

Now, define the function

$$x(t, p) := X_0 e^{\beta p - (e^\beta - 1)\lambda t} \quad (p \in \mathbb{R}) \quad (25)$$

Clearly $X_t = x(t, P_t)$. Applying equation (24) to the function $x(t, p)$ and using that

$$\begin{aligned} \frac{\partial x}{\partial t}(t, p) &= -x(t, p)(e^\beta - 1)\lambda, \\ x(t, p + 1) - x(t, p) &= x(t, p)(e^\beta - 1) \end{aligned} \quad (26)$$

(or alternatively applying Itô's formula to $x(t, P_t)$ and simplifying) yields

$$dX_t = X_{t-}(e^\beta - 1)d(P_t - \lambda t) \quad (27)$$

Next, define the function of $t \leq T$ and $p \in \mathbb{R}$,

$$\begin{aligned} u(t, p) &:= f(t, x(t, p)) \\ &= \sum_{n=0}^{\infty} (X_0 e^{\beta(p+n) - (e^\beta - 1)\lambda T} - 1)^+ \\ &\quad \times \frac{\lambda^n}{n!} (T - t)^n e^{-\lambda(T-t)} \end{aligned} \quad (28)$$

Clearly, $u(t, P_t) = F_t$. One readily verifies that $u(t, p)$ satisfies the equation

$$\frac{\partial u}{\partial t}(t, p) + \lambda(u(t, p + 1) - u(t, p)) = 0 \quad (29)$$

Hence by equation (24) we have,

$$dF_t = (u(t, P_{t-} + 1) - u(t, P_{t-}))d(P_t - \lambda t) \quad (30)$$

Combining this with equation (27) and the fact that clearly

$$\begin{aligned} u(t, p + 1) - u(t, p) &= f(t, e^\beta x(t, p)) \\ &\quad - f(t, x(t, p)) \end{aligned} \quad (31)$$

we conclude that, as desired,

$$dF_t = \frac{f(t, e^\beta X_{t-}) - f(t, X_{t-})}{(e^\beta - 1)X_{t-}} dX_t \quad (32)$$

The Homogeneous Option Price Function

There is an alternative derivation of the self-financing equation $dC = \delta^A dA + \delta^B dB$ much along that in [9] and [8] that does not employ numéraire invariance. It is related to a family of two-dimensional PDEs satisfied by the *Merton/Margrabe homogeneous option price function* $c(t, a, b)$ below.

Let $f(t, x)$, $x > 0$, be any $C^{1,2}$ function, for example, as in equation (6). Define the homogenized function

$$c(t, a, b) := bf\left(t, \frac{a}{b}\right) \quad (a, b > 0) \quad (33)$$

Then $c(t, a, b)$ is homogeneous of degree 1 in (a, b) , and hence by Euler's formula

$$c(t, a, b) = \frac{\partial c}{\partial a}(t, a, b)a + \frac{\partial c}{\partial b}(t, a, b)b \quad (34)$$

A laborious repeated application of the chain rule on equation (33) gives

$$\begin{aligned} a^2 \frac{\partial^2 c}{\partial a^2}(t, a, b) &= b^2 \frac{\partial^2 c}{\partial b^2}(t, a, b) \\ &= -ab \frac{\partial^2 c}{\partial a \partial b}(t, a, b) \\ &= b x^2 \frac{\partial^2 f}{\partial x^2}(t, x), \quad x := \frac{a}{b} \end{aligned} \quad (35)$$

Let $\sigma(t)$, $\sigma_A(t, a, b)$, $\sigma_B(t, a, b)$, $\sigma_{AB}(t, a, b)$ be any functions ($a, b > 0$) such that

$$\sigma^2(t) = \sigma_A^2(t, a, b) + \sigma_B^2(t, a, b) - 2\sigma_{AB}(t, a, b) \quad (36)$$

Using equations (35), (36), and $\frac{\partial c}{\partial t}(t, a, b) = b \frac{\partial f}{\partial t}\left(t, \frac{a}{b}\right)$, we see that $c(t, a, b)$ satisfies the PDE

$$\begin{aligned} \frac{\partial c}{\partial t} + \frac{1}{2} \sigma_A^2(t, a, b) a^2 \frac{\partial^2 c}{\partial a^2} + \frac{1}{2} \sigma_B^2(t, a, b) b^2 \frac{\partial^2 c}{\partial b^2} \\ + \sigma_{AB}(t, a, b) ab \frac{\partial^2 c}{\partial a \partial b} = 0 \end{aligned} \quad (37)$$

if and only if $f(t, x)$ satisfies the PDE (9): $\frac{\partial f}{\partial t} + \frac{1}{2} \sigma^2(t) x^2 \frac{\partial^2 f}{\partial x^2} = 0$.

The PDE (9) was utilized in [1] and [9] (but not in [8]), and Merton [9] stated its equivalence to the PDE (37) (assuming σ_A , etc., depend only on t). As noted in [9] and expounded in [8], if $d[\log A]_t = \sigma_A^2(t)dt$, $d[\log B]_t = \sigma_B^2(t)dt$ and $d[\log A, \log B]_t = \sigma_{AB}(t)dt$, then Itô's formula and equation (37) imply at once $dc(t, A_t, B_t) = \delta_t^A dA_t + \delta_t^B dB_t$, with δ^A and δ^B as in equation (40), and thus (δ^A, δ^B) is an SFTS with price process $c(t, A, B)$ by Euler's formula (34).

Let us expand on this (see also the sections Self-financing Trading Strategies and Homogeneous Continuous Markovian SFTS). Let $\sigma(t) > 0$ be a continuous function, and $f(t, x)$ be the Black-Scholes/Merton function (6). Set $c(t, a, b) := bf(t, a/b)$. Clearly,

$$\frac{\partial c}{\partial a}(t, a, b) = \frac{\partial f}{\partial x}\left(t, \frac{a}{b}\right) = \delta_A\left(t, \frac{a}{b}\right) \quad (38)$$

This combined with Euler's formula (34) and the definition (6) $f := \delta_A x + \delta_B$ give

$$\frac{\partial c}{\partial b}(t, a, b) = \delta_B\left(t, \frac{a}{b}\right) \quad (39)$$

Assume that A and B are positive semimartingales with positive left limits and $X := A/B$ has deterministic volatility $\sigma(t)$: $d[X]_t = X_t^2 \sigma^2(t)dt$. Using equation (12), the deltas are conveniently the sensitivities of the homogeneous Merton/Margrabe function:

$$\delta_t^A = \frac{\partial c}{\partial a}(t, A_t, B_t), \quad \delta_t^B = \frac{\partial c}{\partial b}(t, A_t, B_t) \quad (40)$$

Since X is continuous, we also have $\delta_t^A = \frac{\partial c}{\partial a}(t, A_{t-}, B_{t-})$ and similarly δ_t^B . The section Deterministic-Volatility Exchange Option Model yields $dC = \delta^A dA + \delta^B dB$ with $C_t = B_t f(t, X_t) = c(t, A_t, B_t)$. Therefore, by equation (40) and Itô's formula,

$$\begin{aligned} \frac{\partial c}{\partial t} dt + \frac{1}{2} \frac{\partial^2 c}{\partial a^2} d[A]_t^c + \frac{1}{2} \frac{\partial^2 c}{\partial b^2} d[B]_t^c \\ + \frac{\partial^2 c}{\partial a \partial b} d[A, B]_t^c = 0 \end{aligned} \quad (41)$$

where the partial derivatives are evaluated at (t, A_{t-}, B_{t-}) and $[\cdot]^c$ is the bracket continuous part. (The jump term in Itô's formula vanishes as it equals $\sum_{s \leq t} (\Delta C_s - \delta_s^A \Delta A_s - \delta_s^B \Delta B_s) = 0$.)

Returning to the approach of Merton [9], assume now that $d[\log A]_t = \sigma_A^2(t, A_t, B_t)dt$ for some function σ_A and similarly $d[\log B] = \sigma_B^2 dt$ and $d[\log A, \log B] = \sigma_{AB} dt$. Then equation (36) holds using $\log X = \log A - \log B$. Since $f(t, x)$ satisfies the PDE (9), the PDE (37) follows as before by the chain rule. However, equation (37) implies equation (41), which by Itô's formula in turn implies the self-financing equation $dC = \delta^A dA + \delta^B dB$ with δ^A and δ^B given by equation (40).

Change of Numéraire

The solution $c(t, a, b)$ to the PDE (37) subject to $c(T, a, b) = (a - b)^+$ can be expressed in a form $\mathbb{E}(X - Y)^+$ for some random variables X and $Y > 0$ with means a and b . Expectations of this form often become more tractable by a change of measure as in

[4]. Define the equivalent probability measure $\mathbb{Q}$ by $\frac{d\mathbb{Q}}{d\mathbb{P}} := \frac{Y}{\mathbb{E}Y}$. Clearly,

$$\mathbb{E}^{\mathbb{Q}}\left(\frac{X}{Y}\right) = \frac{\mathbb{E}(X)}{\mathbb{E}(Y)} \quad \left(\frac{d\mathbb{Q}}{d\mathbb{P}} := \frac{Y}{\mathbb{E}(Y)}\right) \quad (42)$$

Replacing X by $(X - Y)^+$ in equation (42) and using the homogeneity to factor out Y , we get

$$\mathbb{E}(X - Y)^+ = \mathbb{E}(Y)\mathbb{E}^{\mathbb{Q}}\left(\frac{X}{Y} - 1\right)^+ \quad (43)$$

If X/Y is $\mathbb{Q}$ -lognormally distributed then equation (43) together with equation (42) readily yields

$$\begin{aligned} \mathbb{E}(X - Y)^+ &= \mathbb{E}(X)N\left(\frac{\log(\mathbb{E}X/\mathbb{E}Y)}{\sqrt{\nu^{\mathbb{Q}}}} + \frac{\sqrt{\nu^{\mathbb{Q}}}}{2}\right) \\ &\quad - \mathbb{E}(Y)N\left(\frac{\log(\mathbb{E}X/\mathbb{E}Y)}{\sqrt{\nu^{\mathbb{Q}}}} - \frac{\sqrt{\nu^{\mathbb{Q}}}}{2}\right) \end{aligned} \quad (44)$$

where $\nu^{\mathbb{Q}} := \text{var}^{\mathbb{Q}}[\log(X/Y)]$. When X and Y are bivariate lognormally distributed, it is not difficult to show that X/Y is lognormally distributed in both $\mathbb{P}$ and $\mathbb{Q}$ with the same log-variance $\nu^{\mathbb{Q}} = \nu := \text{var}[\log(X/Y)]$. Then $\nu^{\mathbb{Q}}$ can be replaced with ν in equation (44). This occurs when the functions σ_A , σ_B and σ_{AB} in equation (37) are independent of a and b , as in [8, 9].

Uniqueness

Assume that A and B are positive semimartingales with positive left limits such that $X := A/B$ is square-integrable martingale under an equivalent probability measure $\mathbb{Q}$ and $d\langle X \rangle_t^{\mathbb{Q}} = X_t^2 \sigma_t^2 dt$ for some nowhere zero process σ , where $\langle X \rangle^{\mathbb{Q}}$ is the $\mathbb{Q}$ -compensator of $[X]$. (Of course, $\langle X \rangle^{\mathbb{Q}} = [X]$ if X is continuous.) Let (δ^A, δ^B) be an SFTS and set $C := \delta^A A + \delta^B B$. We claim that $\delta^A = \delta^B = 0$ if $C_T = 0$ and δ^A is bounded.

Indeed, set $F := C/B$. By numéraire invariance, $dF = \delta^A dX$. Hence, F is a $\mathbb{Q}$ -square-integrable martingale since X is and δ^A is bounded. Thus, $F = 0$ since $F_T = C_T/B_T = 0$. Hence, $0 = d\langle F \rangle_t^{\mathbb{Q}} = (\delta^A)^2 X_t^2 \sigma_t^2 dt$. However, $X_t^2 \sigma_t^2 > 0$. Thus, $\delta^A = 0$ and $\delta^B = F - \delta^A X = 0$.

In general, since $F := C/B$ is a $\mathbb{Q}$ -martingale, we have the following pricing formula:

$$C_t = B_t \mathbb{E}^{\mathbb{Q}}[C_T/B_T | \mathcal{F}_t] \quad (45)$$

Deterministic-volatility Model Uniqueness

Assume that A and B are positive semimartingales with positive left limits and $X := A/B$ is an Itô process following

$$\frac{dX_t}{X_t} = \mu_t dt + \sigma_t dZ_t, \quad \left(X := \frac{A}{B}\right) \quad (46)$$

where Z is a Brownian motion and μ and $\sigma > 0$ are predictable processes with σ bounded and $\mathbb{E}[e^{1/2 \int_0^T (\mu_t/\sigma_t)^2 dt}] < \infty$. Let (δ^A, δ^B) be an SFTS with δ^A bounded. Set $C := \delta^A A + \delta^B B$. We claim that $\delta^A = \delta^B = 0$ if $C_T = 0$. Indeed, the process

$$M := \mathcal{E}\left(-\int \frac{\mu}{\sigma} dZ\right) = e^{-\int \frac{\mu}{\sigma} dZ - \frac{1}{2} \int \left(\frac{\mu}{\sigma}\right)^2 dt} \quad (47)$$

is then a positive martingale with $M_0 = 1$. Define the equivalent probability measure $\mathbb{Q}$ by $d\mathbb{Q} = M_T d\mathbb{P}$. The process $W := Z + \int \frac{\mu}{\sigma} dt$ is a $\mathbb{Q}$ -Brownian motion because $[W]_t = t$ and W is $\mathbb{Q}$ -local martingale as MW is a local martingale using Itô's product rule:

$$\begin{aligned} d(MW) - WdM &= MdW + d[W, M] \\ &= M\left(dZ + \frac{\mu}{\sigma} dt\right) - M\frac{\mu}{\sigma} d[Z] \\ &= MdZ \end{aligned} \quad (48)$$

Moreover, $dX = X\sigma dW$ by equation (46). Therefore, X is a $\mathbb{Q}$ -square integrable martingale since σ is bounded. The claim, thus, follows by the section Uniqueness.

Assume now that σ_t is *deterministic*. The results of the section Deterministic-Volatility Exchange Option Model hold since $d[\log X] = \sigma_t^2 dt$. However, we can now derive them more conceptually. Indeed, both conditioned on $\mathcal{F}_t$ and unconditionally, X_T/X_t is $\mathbb{Q}$ -lognormally distributed with mean 1 and log-variance

$\int_t^T \sigma_s^2 ds$ since $X_T = X_t e^{\int_t^T \sigma_s dW_s - 1/2 \int_t^T \sigma_s^2 ds}$. Hence, by equation (45),

$$f(t, X_t) = \mathbb{E}^{\mathbb{Q}}[(X_T - 1)^+ | \mathcal{F}_t] \quad \text{where}$$

$$f(t, x) := \mathbb{E}^{\mathbb{Q}}\left(x \frac{X_T}{X_t} - 1\right)^+ \quad (49)$$

which function readily equals the Black–Scholes/Merton option price function (6). Thus, $F := (f(t, X_t))$ is a $\mathbb{Q}$ -martingale. Therefore, Itô's formula implies that $f(t, x)$ satisfies the PDE (9) and $dF = \delta^A dX$ where $\delta^A := \frac{\partial f}{\partial x}(t, X_t)$. Numéraire invariance now yields that the pair $(\delta^A, \delta^B := F - \delta^A X)$ is an SFTS. Clearly, $C_T = (A_T - B_T)^+$ where $C := \delta^A A + \delta^B B = BF$.

Exponential-Poisson Model Uniqueness

Let $\beta \neq 0$ be a constant and κ and λ be positive continuous adapted processes such that λ is bounded and $\mathbb{E} \int_0^T \left(\frac{\lambda_t}{\kappa_t} - 1\right)^2 \kappa_t dt < \infty$. Let P be semimartingale satisfying $[P] = P$ with $P_0 = 0$ and compensator $\int \kappa dt$. Assume that A and B are positive semimartingales with positive left limits and $X := \frac{A}{B}$ satisfies

$$dX_t = X_{t-}(e^\beta - 1)(dP_t - \lambda_t dt) \quad (50)$$

Using $de^{\beta P} = (e^\beta - 1)e^{\beta P} dP$ or as in the section Derivation of the Predictable Representation, this is equivalent to the integrated form

$$X_t = X_0 e^{\beta P_t - (e^\beta - 1) \int_0^t \lambda_s ds} \quad (51)$$

Let (δ^A, δ^B) be an SFTS with δ^A bounded. Set $C := \delta^A A + \delta^B B$. We claim that $\delta^A = \delta^B = 0$ if $C_T = 0$. Indeed, $\mathbb{E} \left\langle \int \left(\frac{\lambda}{\kappa} - 1\right) (dP - \kappa dt) \right\rangle_T = \mathbb{E} \int_0^T \left(\frac{\lambda_t}{\kappa_t} - 1\right)^2 \kappa_t dt < \infty$, so the positive local martingale

$$M := \mathcal{E} \left(\int \left(\frac{\lambda}{\kappa} - 1 \right) (dP - \kappa dt) \right)$$

$$= e^{-\int (\lambda - \kappa) dt} \prod_{s \leq \cdot} \left(1 + \left(\frac{\lambda_s}{\kappa_s} - 1 \right) \Delta P_s \right) \quad (52)$$

is a martingale. Define the equivalent probability measure $\mathbb{Q}$ by $d\mathbb{Q} = M_T d\mathbb{P}$. Then $N := P - \int \lambda dt$ is a $\mathbb{Q}$ -local martingale as MN is a local martingale by Itô's product rule:

$$d(MN) - N_- dM = M_- dN + d[M, N]$$

$$= M_- (dP - \lambda dt)$$

$$+ M_- \left(\frac{\lambda}{\kappa} - 1 \right) dP$$

$$= M_- \frac{\lambda}{\kappa} (dP - \kappa dt) \quad (53)$$

Therefore, by equation (50), X is a $\mathbb{Q}$ -square-integrable martingale (in fact, in $\mathcal{H}^p(\mathbb{Q})$ for all $p > 0$) since λ is bounded. Thus, by the section Uniqueness, $\delta^A = \delta^B = 0$ if $C_T = 0$, as claimed.

Assume now that λ is a positive constant. By equation (51) we have a special case of the exponential-Poisson model. Further, P is a $\mathbb{Q}$ -Poisson process with intensity λ since $[P] = P$. We now have uniqueness, but additionally, the previous results follow more conceptually as follows.

Conditioned on $\mathcal{F}_t$, $P_T - P_t$ is $\mathbb{Q}$ -Poisson distributed with mean $\lambda(T - t)$. Its unconditional $\mathbb{Q}$ -distribution is identical. Thus, the $\mathcal{F}_t$ -conditional and the unconditional $\mathbb{Q}$ -distribution of X_T/X_t are identical and are exponentially Poisson distributed with mean 1. Hence, by equation (45),

$$f(t, X_t) = \mathbb{E}^{\mathbb{Q}}[(X_T - 1)^+ | \mathcal{F}_t] \quad \text{where}$$

$$f(t, x) := \mathbb{E}^{\mathbb{Q}}\left(x \frac{X_T}{X_t} - 1\right)^+ \quad (54)$$

which function readily equals that defined in equation (16). Thus, $F := (f(t, X_t))$ is a $\mathbb{Q}$ -martingale. Using this and equation (24), one shows that F satisfies equation (32) and with it that the pair (δ^A, δ^B) as defined in equation (19), equation (20) is a bounded SFTS for the exchange option.

Extension to Dividends

Consider two assets with positive price processes $\hat{A}$ and $\hat{B}$ and continuous dividend yields y_t^A and y_t^B . When there exist traded or replicable zero-dividend assets A and B such that $A_T = \hat{A}_T$ and $B_T = \hat{B}_T$ (if not, there is little hope of replication), it is natural to

define the price process of the option to exchange $\hat{A}$ and $\hat{B}$ to be that of the option to exchange A and B . If y^A and y^B are deterministic, then consistent with the treatment of dividends in [9], A (and similarly B) is simply given by

$$\begin{aligned} A_t &:= a\tilde{A}_t = e^{-\int_t^T y_s^A ds} \hat{A}_t, \\ \tilde{A}_t &:= e^{\int_0^t y_s^A ds} \hat{A}_t, \quad a := e^{-\int_0^T y_t^A dt} \end{aligned} \quad (55)$$

Note A/B is a semimartingale if and only if $\hat{A}/\hat{B}$ is, in which case $[\log A/B] = [\log \hat{A}/\hat{B}]$.

In general, $\tilde{A}_t$ is the price of the zero-dividend asset that initially buys one share of $\hat{A}$ and thereon continually reinvests all dividends in $\hat{A}$ itself. What is required is that the four zero-dividend assets A , $\tilde{A}$, B , and $\tilde{B}$ be arbitrage free in relation to one another (see the section Arbitrage-free Semimartingales and Uniqueness).

For instance, say $\hat{A}$ and $\hat{B}$ are the yen/dollar and yen/Euro exchange rates viewed as yen-denominated dividend assets. Then A is the yen-value of the US T -maturity zero-coupon bond and $\tilde{A}$ is the yen-value of the US money market asset. This exchange option is equivalent to a Euro-denominated call struck at 1 on the Euro/dollar exchange rate $\hat{A}/\hat{B}$. The ratio A/B is the *forward* Euro/dollar exchange rate. If it has deterministic volatility, we are as in a setting of [7], which yields the same pricing formula as that from the section Deterministic-volatility Exchange Option Model.

Pricing and Hedging Options with Homogeneous Payoffs

We took some shortcuts to quickly present the main results for two of the simplest and among the most interesting examples. A better understanding of the principles at work requires generalization to contingent claims C on many assets with price processes $A = (A^1, \dots, A^m) > 0$ and a path-independent payoff $C_T = h(A_T)$ given as a homogeneous function $h(a)$, $a \in \mathbb{R}_+^m$, of the asset prices A_T at expiration time T . Combined with an underlying SDE and the resulting PDE, such a Markovian setting utilizes the invariance principle and equivalent martingale measures to derive unique pricing and construct an SFTS that

replicates the given payoff $h(A_T)$ in general. The construction is explicit in the multivariate extensions of the deterministic-volatility and exponential-Poisson models.

The homogeneity of the payoff function $h(a)$ implies $h(A_T) = A_T^m g(X_T)$ where $g(x) := h(x, 1)$, $x \in \mathbb{R}_+^n$, $n := m - 1$, and $X := \left(\frac{A^1}{A^m}, \dots, \frac{A^n}{A^m}\right)$. Once a predictable representation $F = F_0 + \delta' \cdot X$, $F_T = g(X_T)$ is found, then by numéraire invariance $\delta := (\delta', \delta^m)$ will be an SFTS with payoff $h(A_T)$, where $\delta^m := F_- - \sum_{i=1}^n \delta^i X_- = F - \sum_{i=1}^n \delta^i X$. Uniqueness of pricing requires boundedness of partial derivatives (or differences) of $h(a)$ (or $g(x)$) and that A be arbitrage free, meaning X is a martingale under an equivalent measure. Arbitrage freedom holds “generically” when the matrix $(\langle X^i, X^j \rangle)$ is nonsingular, basically a “no-redundant-asset” condition. Then the SFTS is also unique.

Libor and swap derivatives are among contingent claims with homogeneous payoffs.

Self-financing Trading Strategies

By an SFTS we mean a pair (δ, A) of an m -dimensional semimartingale $A = (A^1, \dots, A^m)$ and an A -integrable predictable vector process $\delta = (\delta^1, \dots, \delta^m)$ such that (with $\delta \cdot A$ denoting the m -dimensional stochastic integral)

$$\sum_{i=1}^m \delta^i A^i = \sum_{i=1}^m \delta_0^i A_0^i + \delta \cdot A \quad (56)$$

We then say δ is an SFTS for A . This is equivalent to saying that the SFTS price process

$$C := \sum_{i=1}^m \delta^i A^i \quad (57)$$

satisfies $C = C_0 + \delta \cdot A$. Clearly, C is then a semimartingale, $\Delta C = \sum_i \delta^i \Delta A_i$, and hence

$$C_- = \sum_{i=1}^m \delta^i A_-^i \quad (58)$$

If δ^i are bounded (say by b) and A^i are martingales, then the SFTS price process C is a martingale

because C is then a local martingale that is dominated by a martingale M :

$$\begin{aligned} |C_t| &\leq b \sum_i |A_t^i| = b \sum_i |\mathbb{E}[A_T^i | \mathcal{F}_t]| \\ &\leq b \sum_i \mathbb{E}[|A_T^i| | \mathcal{F}_t] =: M_t \end{aligned} \quad (59)$$

As suggested by the case of a locally bounded δ , we often use the differential form

$$dC = \sum_{i=1}^m \delta^i dA^i \quad (60)$$

of the equation $C = C_0 + \delta \cdot A$ as a convenient symbolic equivalent in calculations. One interprets A^i as prices of m zero-dividend assets and δ_t^i as the number of shares invested in them at time t . Then C_t indicates the resultant self-financing portfolio price by equation (57), and equation (60) is the self-financing equation, implying that the change dC in the portfolio price is only due to the changes dA^i in the asset prices with no financing from outside.

Assume for the remainder of this subsection as a way of motivation that A is continuous and $C_t = c(t, A_t)$ for some $C^{1,2}$ function $c(t, a)$.^a Then by equation (60) and Itô's formula, we have

$$\begin{aligned} \frac{\partial c}{\partial t}(t, A_t)dt + \frac{1}{2} \sum_{i,j=1}^m \frac{\partial^2 c}{\partial a_i \partial a_j}(t, A_t) d[A^i, A^j]_t \\ = \sum_{i=1}^m \left(\delta_t^i - \frac{\partial c}{\partial a_i}(t, A_t) \right) dA_t^i \end{aligned} \quad (61)$$

In particular, if $\delta_t^i = \frac{\partial c}{\partial a_i}(t, A_t)$ for all i then $c(t, A_t) = \sum_i \frac{\partial c}{\partial a_i}(t, A_t) A_t^i$ by equation (57) and

$$\frac{\partial c}{\partial t}(t, A_t)dt + \frac{1}{2} \sum_{i,j=1}^m \frac{\partial^2 c}{\partial a_i \partial a_j}(t, A_t) d[A^i, A^j]_t = 0 \quad (62)$$

In general, $\sum_{i,j} \left(\delta^i - \frac{\partial c}{\partial a_i} \right) \left(\delta^j - \frac{\partial c}{\partial a_j} \right) d[A^i, A^j] = 0$ since the (left) right-hand side of equation

(61) has finite variation. Thus, if $[A^i]$ are absolutely continuous and the $m \times m$ matrix $(d/dt[A^i, A^j])$ is nonsingular, then $\delta_t^i = \partial c / \partial a_i(t, A_t)$, so equation (62) holds and $c(t, A_t) = \sum_i \partial c / \partial a_i(t, A_t) A_t^i$. If further the support of A_t is a cone, it follows $c(t, a)$ is *homogeneous of degree 1* in a on that cone.

Assume that $M^i := e^{-\int r dt} A^i$ are local martingales under an equivalent measure for some locally bounded predictable process r . Then $dA^i = r A^i dt + e^{\int r dt} dM^i$; thus, by equations (61) and (57)

$$\begin{aligned} \frac{\partial c}{\partial t}(t, A_t)dt + \frac{1}{2} \sum_{i,j=1}^m \frac{\partial^2 c}{\partial a_i \partial a_j}(t, A_t) d[A^i, A^j]_t \\ = r_t \left(C_t - \sum_{i=1}^m \frac{\partial c}{\partial a_i}(t, A_t) A_t^i \right) dt \end{aligned} \quad (63)$$

Hence, if $c(t, a)$ is homogeneous (in a), then by Euler's formula equation (62) holds (yet δ_t^i may differ from $\partial c / \partial a_i(t, A_t)$ if there are redundancies, for then a regular replicating SFTS is not unique).

Given a homogeneous payoff function $h(a)$, the section Homogeneous Continuous Markovian SFTS constructs under suitable assumptions a homogeneous solution $c(t, a)$ to equation (62) with $c(T, a) = h(a)$. Clearly then, by Euler and Itô formulae, $(\partial c / \partial a_i(t, A_t))$ is an SFTS for A (as observed in [9] and highlighted in [8], see the section The Homogeneous Option Price Function). To this end, we first factor out the homogeneous symmetry of $h(a)$ next.

The Invariance Principle

Let (δ, A) be an SFTS and S a (scalar) semimartingale such that δ is $SA := (SA^1, \dots, SA^m)$ -integrable. Then (δ, SA) is an SFTS. Consequently,

$$d(SC) = \sum_{i=1}^m \delta^i d(SA^i) \quad (64)$$

where $C := \sum_i \delta^i A^i = C_0 + \delta \cdot A$, that is, $SC = S_0 C_0 + \delta \cdot (SA)$. Indeed, by Itô's product rule, then substituting for dC and C_- and regrouping, followed

by Itô's product rule again,

$$\begin{aligned}
d(SC) &= S_-dC + C_-dS + d[S, C] \\
&= S_- \sum_{i=1}^m \delta^i dA^i + \sum_{i=1}^m \delta^i A_-^i dS + \sum_{i=1}^m \delta^i d[S, A^i] \\
&= \sum_{i=1}^m \delta^i (S_-dA^i + A_-^i dS + d[S, A^i]) \\
&= \sum_{i=1}^m \delta^i d(SA^i) \tag{65}
\end{aligned}$$

Interpreting S as an exchange rate, this result [3, 4, 8], called *numéraire invariance*, means that the self-financing property is independent of the base currency. (To the best of our knowledge, the term was coined in the 1992 edition of [3], where a similar proof is given.)

If $S, S_- > 0$, then applied to the semimartingale $1/S$ we see that δ is an SFTS for A if and only if it is one for SA . Thus, if equation (57) holds, then equations (60) and (64) are equivalent.

Assume now that $A^m, A_-^m > 0$ and $m \geq 2$. Define the $n := m - 1$ dimensional semimartingale

$$X := \left(\frac{A^1}{A^m}, \dots, \frac{A^n}{A^m} \right), \quad n := m - 1 \tag{66}$$

Taking $S = 1/A^m$, it follows that δ is an SFTS for A if and only if it is an SFTS for $A/A^m = (X, 1)$, that is, if and only if $F := C/A^m$ satisfies $F = F_0 + \delta' \cdot X$ where $\delta' := (\delta^1, \dots, \delta^n)$. Clearly in this case, $F = \sum_{i=1}^n \delta^i X^i + \delta^m$ and $F_- = \sum_{i=1}^n \delta^i X_-^i + \delta^m$ as $\Delta F = \delta' \cdot \Delta X$. Thus,

$$\delta^m = F - \sum_{i=1}^n \delta^i X^i = F_- - \sum_{i=1}^n \delta^i X_-^i, \quad \left(F := \frac{C}{A^m} \right) \tag{67}$$

(When $m = 1$, a similar argument shows that δ must be a constant, as intuitively obvious.)

Conversely, suppose that δ' is an X -integrable process and F is a process such that $F = F_0 + \delta' \cdot X$. Define δ^m by either of the above formulas—the other then holds as before. Obviously then $\delta = (\delta', \delta^m)$ is an SFTS for $(X, 1)$ with price process F . Hence by

numéraire invariance, δ is an SFTS for A with price process $C = A^m F$, provided δ is A -integrable.

Thus, numéraire invariance shows that *in order to find an SFTS with a given time- T payoff C_T it is sufficient to find processes δ' and F such that $F = F_0 + \delta' \cdot X$ and $F_T = C_T/A_T^m$.*

Since $\delta^m = F - \sum_{i=1}^n \delta^i X^i$, the m th delta δ^m is like F determined by δ' and F_0 . As such, one interprets the m -th asset as the “numéraire asset” chosen to finance an otherwise arbitrary trading strategy δ' in the other assets, post an initial investment of $C_0 = A_0^m F_0$.

We often use the differential form $dF = \sum_{i=1}^n \delta^i dX^i$ of the equation $F = F_0 + \delta' \cdot X$.

Arbitrage-free Semimartingales and Uniqueness

We call a semimartingale $A = (A^1, \dots, A^m)$, $m \geq 2$, *arbitrage free* if there exists a positive semimartingale S with $S_- > 0$ such that SA^i are martingales for all i . Such a process S is called a *state price density* or *deflator* for A . The *law of one price* (with bounded deltas) justifies the terminology:

If A is arbitrage free and δ is a bounded SFTS for A , then SC is a martingale where $C := \sum_{i=1}^m \delta^i A^i$; consequently, $C = 0$ if $C_T = 0$.

Indeed, by numéraire invariance δ is then an SFTS for SA with price process SC . Hence by the section Self-financing Trading Strategies, SC is a martingale, implying $SC = 0$ if $C_T = 0$, and with it $C = 0$, as claimed.

A simple and well-known argument yields that *if $A^m, A_-^m > 0$, then A is arbitrage free if and only if there exists an equivalent probability measure $\mathbb{Q}$ such that X is a $\mathbb{Q}$ -martingale, where $X := \left(\frac{A^1}{A^m}, \dots, \frac{A^n}{A^m} \right)$, $n := m - 1$.*^b Numéraire invariance then implies that C/A^m is a $\mathbb{Q}$ -martingale for the price process $C := \sum_i \delta^i A^i$ of any bounded SFTS δ , and hence

$$C_t = A_t^m \mathbb{E}^{\mathbb{Q}} \left[\frac{C_T}{A_T^m} \mid \mathcal{F}_t \right] \tag{68}$$

Indeed, by numéraire invariance, δ is an SFTS for A/A^m with price process C/A^m . Hence, C/A^m is a $\mathbb{Q}$ -martingale by the section Self-Financing Trading Strategies since A/A^m is a $\mathbb{Q}$ -martingale and δ is bounded.

Suppose that X is a $\mathbb{Q}$ -square-integrable martingale and δ^i are bounded for $i \leq n$. Then $F := C/A^m$ is a $\mathbb{Q}$ -square-integrable martingale

since $dF = \sum_{i=1}^n \delta^i dX^i$ by numéraire invariance. Moreover, $d\langle F \rangle^{\mathbb{Q}} = \sum_{i,j=1}^n \delta^i \delta^j d\langle X^i, X^j \rangle^{\mathbb{Q}}$. Thus, if $\langle X^i \rangle^{\mathbb{Q}}$ are absolutely continuous and the $n \times n$ matrix $(d/dt \langle X^i, X^j \rangle^{\mathbb{Q}})$ is nonsingular, then given any random variable R , there exists at most one SFTS δ for A such that $\sum_{i=1}^m \delta_T^i A_T^i = R$ and δ^i are bounded for $i \leq n$.

Projective Continuous Markovian SFTS

Let $X = (X^1, \dots, X^n)$ be a continuous vector martingale. In this, subsection $x \in \mathbb{R}_+^n$ if $X > 0$ (the main case of interest); otherwise, $x \in \mathbb{R}^n$. Let $g(x)$ be a Borel function of linear growth (so $\mathbb{E}|g(X_T)| < \infty$), and $f(t, x)$ be a continuous function, $C^{1,2}$ on $t < T$. Set $m := n + 1$ and define the C^1 functions

$$\begin{aligned} \delta_i(t, x) &:= \frac{\partial f}{\partial x_i}(t, x), \quad i \leq n, \\ \delta_m(t, x) &:= f(t, x) - \sum_{i=1}^n \delta_i(t, x) x_i \end{aligned} \quad (69)$$

and the continuous vector process

$$\delta = (\delta^1, \dots, \delta^m), \quad \delta_t^i := \delta_i(t, X_t) \quad (70)$$

First suppose that

$$f(t, X_t) = \mathbb{E}[g(X_T) | \mathcal{F}_t] \quad (71)$$

Then the process $F := (f(t, X_t))$ is a martingale, and since X^i are also martingales, Itô's formula yields

$$dF_t = \sum_{i=1}^n \frac{\partial f}{\partial x_i}(t, X_t) dX_t^i, \quad (72)$$

and

$$\frac{\partial f}{\partial t}(t, X_t) dt + \frac{1}{2} \sum_{i,j=1}^n \frac{\partial^2 f}{\partial x_i \partial x_j}(t, X_t) d[X^i, X^j]_t = 0 \quad (73)$$

Clearly, $F_T = g(X_T)$ and equation (72) imply δ is an SFTS for $(X, 1)$ with price process F .

Conversely, suppose that $f(t, x)$ satisfies equation (73) or equivalently, by Itô's formula, equation (72). By equation (72), δ is an SFTS for $(X, 1)$ with price process $F := f(t, X_t)$. Thus by the section Self-financing Trading Strategies, if $\delta_i(t, x)$ are bounded then F is a martingale and if further $f(T, x) = g(x)$ then equation (71) holds. Moreover, as in the section Arbitrage-free Semimartingales and Uniqueness, δ given by equation (70) is then the

unique bounded SFTS for $(X, 1)$ with payoff $g(X_T)$, provided $d[X^i, X^j] = X^i X^j \sigma^{ij} dt$ for some nonsingular matrix process (σ_t^{ij}) .

Example: Projective Deterministic Volatility

Let $X = (X^1, \dots, X^n) > 0$ be a continuous n -dimensional martingale such that

$$d[X^i, X^j]_t = X_t^i X_t^j \sigma_{ij}(t) dt \quad (74)$$

for some n^2 deterministic continuous functions $\sigma_{ij}(t)$. So, $d[\log X^i, \log X^j]_t = \sigma_{ij}(t) dt$. Conditioned on $\mathcal{F}_t$ and unconditionally, X_T/X_t is then *multivariately lognormally distributed*, with mean $(1, \dots, 1)$ and log-covariance matrix $(\int_t^T \sigma_{ij}(s) ds)$. Let $P(t, T, z)$ denote its distribution function. Let $g(x)$ be a Borel function of linear growth. Define the function

$$f(t, x) := \mathbb{E} \left[g \left(x_1 \frac{X_T^1}{X_t^1}, \dots, x_n \frac{X_T^n}{X_t^n} \right) \right] \quad (75)$$

Obviously, $f(T, x) = g(x)$. Clearly, $f(t, x)$ can also be represented in two other ways as

$$\begin{aligned} f(t, x) &= \int_{\mathbb{R}_+^n} g(x_1 z_1, \dots, x_n z_n) P(t, T, dz) \\ &= \mathbb{E} \left[g \left(x_1 \frac{X_T^1}{X_t^1}, \dots, x_n \frac{X_T^n}{X_t^n} \right) \middle| \mathcal{F}_t \right] \end{aligned} \quad (76)$$

Equation (71) holds by the second equality, and $f(t, x)$ is C^1 in t and smooth (even analytic) in x on $t < T$ as seen by changing variable in the integral to $y^i = x^i z^i$ and differentiating under the integral sign in the first equality. Therefore by equation (73), $f(t, x)$ satisfies the PDE

$$\frac{\partial f}{\partial t} + \frac{1}{2} \sum_{i,j=1}^n \sigma_{ij}(t) x_i x_j \frac{\partial^2 f}{\partial x_i \partial x_j} = 0 \quad (77)$$

on the support of X , equation (72) holds, and δ is an SFTS for $(X, 1)$ with price process $F := (f(t, X_t))$, a martingale by equation (71). If $g(x)$ is dx -absolutely continuous with bounded partial derivatives $\frac{\partial g}{\partial x_i}$ (as L^1_{loc} functions), then $g(x)$ has linear growth, $\mathbb{E}|g(X_T)|^p < \infty$ for $p > 0$, and

$$\frac{\partial f}{\partial x_i}(t, x) = \mathbb{E} \left[\frac{X_T^i}{X_t^i} \frac{\partial g}{\partial x_i} \left(x_1 \frac{X_T^1}{X_t^1}, \dots, x_n \frac{X_T^n}{X_t^n} \right) \right] \quad (78)$$

Thus, $\delta_i(t, x) = \frac{\partial f}{\partial x_i}(t, x)$ are bounded. If $g(x) - \sum \frac{\partial g}{\partial x_i} x_i$ is bounded, then so is $\delta_m(t, x)$ as

$$\delta_m(t, x) = \mathbb{E} \left[g \left(x \frac{X_T}{X_t} \right) - \sum_{i=1}^n \frac{\partial g}{\partial x_i} \left(x \frac{X_T}{X_t} \right) \frac{X_T^i}{X_t^i} \right] \quad (79)$$

It further follows that if $f(t, x)$ is any $C^{1,2}$ function with bounded partials $\frac{\partial f}{\partial x_i}(t, x)$ satisfying $f(T, x) = 0$ for all x and the PDE (77), then $F := (f(t, X_t)) = 0$. Indeed, equation (72) then holds by PDE (77) and Itô's formula, implying F is a square-integrable martingale. Thus $F = 0$ since $F_T = 0$. As such, $f(t, x) = 0$ identically if the support of X_t equals $\mathbb{R}_+^n$ for every t . This is so if the matrix $(\sigma_{ij}(t))$ is nonsingular at least near 0, and it is "generically" so even when the matrix has rank 1 but is time dependent.

Projective Continuous SDE SFTS

Continuous Markovian positive martingales $X = (X^1, \dots, X^n)$ often arise as solutions to an SDE system of the form

$$dX_t^i = X_t^i \sum_{j=1}^k \varphi_{ij}(t, X_t) dW_t^j \quad (80)$$

where $W^1, \dots, W^k$ are independent Brownian motions and $\varphi_{ij}(t, x)$, $x \in \mathbb{R}_+^n$, are continuous bounded functions. As is well known, for each $s \leq T$ and $x \in \mathbb{R}_+^n$, there is a unique continuous semimartingale $X^{s,x} = (X_t^{s,x})$ on $[s, T]$ with $X_s^{s,x} = x$ satisfying this SDE; moreover, $X^{s,x}$ is a positive square-integrable martingale (in fact in all $\mathcal{H}^p$) since $\varphi_{ij}(t, x)$ are bounded. Fixing an $X_0 \in \mathbb{R}_+^n$, the solution on $[0, T]$ starting at X_0 at time 0 is denoted as $X = X^{0,X_0}$. The Markov property holds: for any Borel function $g(x)$ of linear growth,

$$\mathbb{E}[g(X_T) | \mathcal{F}_t] = f(t, X_t) \quad \text{where} \quad f(t, x) := \mathbb{E} g(X_T^{t,x}) \quad (81)$$

Clearly $f(T, x) = g(x)$. (Intuitively, $f(t, x) = \mathbb{E}[g(X_T) | X_t = x]$.)

Thus if we assume that $\varphi_{ij}(t, x)$ are sufficiently regular so that $f(t, x)$ is $C^{1,2}$ on $t < T$ for every

bounded (hence of linear growth) Borel function $g(x)$, then the assumptions of the section Projective Continuous Markovian SFTS are satisfied and the conclusions hold. In particular, equation (72) then holds, and since

$$d[X^i, X^j] = X^i X^j \sigma_{ij}(t, X) dt \quad \text{where} \quad \sigma_{ij}(t, x) := \sum_{l=1}^k \varphi_{il}(t, x) \varphi_{jl}(t, x) \quad (82)$$

it follows from equation (73) that, at least on the support of X , $f(t, x)$ satisfies the PDE

$$\frac{\partial f}{\partial t}(t, x) + \frac{1}{2} \sum_{i,j=1}^n x_i x_j \sigma_{ij}(t, x) \frac{\partial^2 f}{\partial x_i \partial x_j}(t, x) = 0 \quad (83)$$

In the deterministic-volatility case, the functions φ_{ij} and hence σ_{ij} are independent of x and simply $X_T^{t,x} = x X_T / X_t$, explaining why in this special case $f(t, x)$ is also given by equation (73).

In general, if $g(x)$ is absolutely continuous with bounded derivatives and the probability transition function of X is sufficiently regular, one shows, as in the deterministic volatility case, that the x -partial derivatives of f (the deltas) are bounded and thereby concludes uniqueness.

If $\sigma_{ij}(t, x)$ are homogeneous of degree 0 in x , then (assumed) uniqueness and symmetry of PDE (73) under dilation in x imply that $f(t, x)$ is homogeneous of degree 1 in x if $g(x)$ is so. By Euler's formula then $\delta_m(t, x) = 0$ in equation (69), implying $(\delta^1, \dots, \delta^n)$ is an SFTS for X .

Homogeneous Continuous Markovian SFTS

Let $A = (A^1, \dots, A^m)$ be a semimartingale with $A, A_- > 0$ such that $X^i := A^i / A^m$ are Itô processes following

$$dX_t^i = X_t^i \sum_{j=1}^k \varphi_t^{ij} (dZ_t^j + \phi_t^j dt) \quad (i = 1, \dots, n := m - 1) \quad (84)$$

where Z^j are independent Brownian motions and ϕ^j , φ^{ij} are locally bounded predictable processes with

φ^{ij} bounded and $\mathbb{E} e^{1/2 \sum_j \int_0^T (\phi_j^i)^2 dt} < \infty$. Define the martingale

$$\begin{aligned} M &:= \mathcal{E} \left(- \sum_{j=1}^k \int \phi^j dZ^j \right) \\ &= e^{-\sum_{j=1}^k \left(\int \phi^j dZ^j + \frac{1}{2} \int (\phi^j)^2 dt \right)} \end{aligned} \quad (85)$$

and the measure $\mathbb{Q}$ by $d\mathbb{Q} = M_T d\mathbb{P}$. Then $W^i := Z^i + \int \phi^i dt$ are $\mathbb{Q}$ -Brownian motions and are $\mathbb{Q}$ -independent since $[W^k, W^l] = 0$ for $k \neq l$. Hence, X^i are $\mathbb{Q}$ -square-integrable martingales as $dX^i = X^i \sum_{j=1}^k \varphi^{ij} dW^j$ and φ^{ij} are bounded. Thus, A is arbitrage free.

Now let $h(a)$, $a \in \mathbb{R}_+^m > 0$, be a homogeneous function of linear growth. Define $g(x) := h(x, 1)$, $x \in \mathbb{R}_+^n$. Assume further that $\varphi_i^{ij} = \varphi_{ij}(t, X_t)$ for some continuous bounded functions $\varphi_{ij}(t, x)$. Then equation (80) holds, and hence the section Projective Continuous SDE SFTS applied under measure $\mathbb{Q}$ shows that X is $\mathbb{Q}$ -Markovian in that $\mathbb{E}^{\mathbb{Q}}[g(X_T) | \mathcal{F}_t] := f(t, X_t)$ where $f(t, x) = \mathbb{E}^{\mathbb{Q}}[g(X_T^{t,x})]$, as in equation (81). Thus, by the section Projective Continuous SDE SFTS, equations (72) and (73) hold and δ as defined in equation (70) is an SFTS for $(X, 1)$. Therefore by numéraire invariance, δ is an SFTS for A with price process $C = A^m F$. The homogeneity of $h(a)$ further implies $C_T = A_T^m g(X_T) = h(A_T)$.

We have thus constructed an SFTS with the given payoff $h(A_T)$. As in the section Example: Projective Deterministic Volatility or Projective Continuous SDE SFTS, we ensure its boundedness by requiring the x -partial derivatives of $g(x)$ or equivalently a -partial derivatives of $h(a)$ (as L_{loc}^1 functions) be bounded and thereby get unique pricing. For (very) low dimensions n , the PDE (83) is suitable for numerical valuation in the absence of a closed-form solution.

Although the option price process and the deltas are already found, let us also consider the homogeneous option price function referred to in the section Self-financing Trading Strategies, and now naturally defined by

$$c(t, a) := a_m f \left(t, \frac{a^1}{a^m}, \dots, \frac{a^n}{a^m} \right) \quad (86)$$

Then $C_t = c(t, A_t)$. Agreeably, $\delta_t^i = \frac{\partial c}{\partial a_i}(t, A_t)$ by equation (69). (For $i = m$ use Euler's formula for $c(t, a)$.) By the continuity of X and equation (69), $\delta_t^i = \frac{\partial c}{\partial a_i}(t, A_{t-})$ too. Therefore by Itô's formula,

$$\frac{\partial c}{\partial t}(t, A_{t-})dt + \frac{1}{2} \sum_{i,j=1}^m \frac{\partial^2 c}{\partial a_i \partial a_j}(t, A_{t-})d[A^i, A^j]_t^c = 0 \quad (87)$$

(The term for the sum of jumps in Itô's formula vanishes since $\Delta C = \sum \delta^i \Delta A^i$.) This yields the PDE $\frac{\partial c}{\partial t} + \frac{1}{2} \sum_{i,j} a_i a_j \sigma_{ij}^A(t, a) \frac{\partial^2 c}{\partial a_i \partial a_j} = 0$ for the special case $d[A^i, A^j]_t = A_t^i A_t^j \sigma_{ij}^A(t, A_t)dt$ for some functions $\sigma_{ij}^A(t, a)$. The quotient-space PDE (83) is more fundamental for it holds in general (even when A is discontinuous) and has one lower dimension. Change of variable $L^i = \frac{X^i}{X^{i+1}} - 1$ ($i < n$), $L^n = X^n - 1$, transforms equation (83) to the Libor market model PDE.

Multivariate Poisson Predictable Representation

Let $P = (P^1, \dots, P^k)$ be a vector of independent Poisson processes P^i with intensities $\lambda_i > 0$. For any C^1 in t function $u(t, p)$, $p \in \mathbb{R}^k$, the process $u(t, P) = (u(t, P_i))$ is a finite activity semimartingale, and using $[P^i, P^j] = 0$, one has $\Delta u(t, P) = \sum_i \Delta_i u(t, P_-) \Delta P^i$, where

$$\Delta_i u(t, p) := u(t, p_1, \dots, p_i + 1, \dots, p_n) - u(t, p) \quad (88)$$

denotes the i th forward partial difference of $u(t, p)$ in p . This in turn readily implies

$$du(t, P) = \frac{\partial u}{\partial t}(t, P_-)dt + \sum_{i=1}^k \Delta_i u(t, P_-)dP^i \quad (89)$$

Let $v(p)$, $p \in \mathbb{R}^k$ be a function of exponential linear growth. Define the function

$$\begin{aligned} u(t, p) &:= \sum_{q_1, \dots, q_k=0}^{\infty} v(p + q) \\ &\times \prod_{i=1}^k \frac{\lambda_i^{q_i}}{q_i!} (T - t)^{q_i} e^{-\lambda_i(T-t)} \quad (p \in \mathbb{R}^k) \end{aligned} \quad (90)$$

Clearly, $u(T, p) = v(p)$. Since the unconditional distribution of P_{T-} is Poisson and is the same as the distribution of $P_T - P_t$ conditioned on $\mathcal{F}_t$, we have

$$\begin{aligned} u(t, p) &= \mathbb{E}[v(p + P_T - P_t)] \\ &= \mathbb{E}[v(p + P_T - P_t) | \mathcal{F}_t] \end{aligned} \quad (91)$$

Hence, $u(t, P_t) = \mathbb{E}[v(P_T) | \mathcal{F}_t]$. (Intuitively, $u(t, p) = \mathbb{E}[v(P_T) | P_t = p]$.) Thus, the process

$$F = (F_t), \quad F_t := u(t, P_t) = \mathbb{E}[v(P_T) | \mathcal{F}_t] \quad (92)$$

is a martingale. But so are $P^j - \lambda_j t$. Therefore in view of equation (89), it follows that

$$dF = \sum_{i=1}^k \Delta_i u(t, P_-) d(P^i - \lambda_i t) \quad (93)$$

and $u(t, p)$ satisfies the equation

$$\frac{\partial u}{\partial t}(t, P_{t-}) + \sum_{i=1}^k \lambda_i \Delta_i u(t, P_{t-}) = 0 \quad (94)$$

Since $F_T = v(P_T)$ and $F_0 = u(0, 0)$, combining equations (90) and (93) yields the following representation:

$$\begin{aligned} v(P_T) &= \sum_{q_1, \dots, q_k=0}^{\infty} v(q_1, \dots, q_k) \prod_{i=1}^k \frac{\lambda_i^{q_i}}{q_i!} T^{q_i} e^{-\lambda_i T} \\ &\quad + \sum_{i=1}^k \int_0^T \Delta_i u(t, P_{t-}) d(P_t^i - \lambda_i t) \end{aligned} \quad (95)$$

Projective Exponential-Poisson SFTS

Let $P = (P^1, \dots, P^k)$ be a vector of independent Poisson processes P^j with intensities $\lambda_j > 0$. Let $X_0 \in \mathbb{R}_+^n$, $n \geq k$, and $\beta = (\beta_{ij})$ be an $n \times k$ matrix such that the $n \times k$ matrix $(e^{\beta_{ij}} - 1)$ has full rank. Then the processes $X^i := (x_i(t, P_t))$, $i = 1, \dots, n$, are square-integrable martingales (in fact in all $\mathcal{H}^p$), where

$$\begin{aligned} x_i(t, p) &:= X_0^i \exp \left(\sum_{j=1}^k (\beta_{ij} p_j - (e^{\beta_{ij}} - 1) \lambda_j t) \right) \\ (p \in \mathbb{R}^k) \end{aligned} \quad (96)$$

Since

$$\begin{aligned} \frac{\partial x_i}{\partial t}(t, p) &= -x_i(t, p) \sum_{j=1}^k (e^{\beta_{ij}} - 1) \lambda_j, \\ \Delta_j x_i(t, p) &= x_i(t, p) (e^{\beta_{ij}} - 1) \end{aligned} \quad (97)$$

it follows from equation (89) (or easily also from Itô's formula) that

$$\begin{aligned} dX^i &= X_-^i \sum_{j=1}^k (e^{\beta_{ij}} - 1) \\ &\quad \times d(P^j - \lambda_j t) \quad (X_t^i := x_i(t, P_t)) \end{aligned} \quad (98)$$

Let $\alpha = (\alpha_{ij})$ be any $n \times k$ matrix such that $\sum_i (e^{\beta_{il}} - 1) \alpha_{ij} = \delta_{jl}$, all $1 \leq j, l \leq k$. Then

$$d(P^j - \lambda_j t) = \sum_{i=1}^n \alpha_{ij} \frac{dX^i}{X_-^i} \quad (99)$$

Now let $g(x)$, $x \in \mathbb{R}_+^n$, be a function of linear growth; define the function

$$v(p) := g(x_1(T, p), \dots, x_n(T, p)), \quad (p \in \mathbb{R}^n) \quad (100)$$

and the function $u(t, p)$ by equation (90). By the section Multivariate Poisson Predictable Representation, $F := (u(t, P_t))$ is a martingale with $F_T = v(P_T) = g(X_T)$ and is represented as equation (93). Substituting equation (99) into equation (93) yields

$$dF = \sum_{i=1}^n \delta^i dX^i \quad (101)$$

where

$$\delta_t^i := \frac{1}{X_{t-}^i} \sum_{j=1}^k \alpha_{ij} \Delta_j u(t, P_{t-}) \quad (102)$$

Thus, $\delta = (\delta^1, \dots, \delta^m)$ is an SFTS for $(X, 1)$ where $m := n + 1$ and $\delta^m := F - \sum_{i=1}^n \delta^i X^i$.

It is more desirable to express δ in terms of X . One has $u(t, p) = f(t, x(t, p))$, where

$$\begin{aligned}
f(t, x) &:= \mathbb{E} \left[g \left(x \frac{X_T}{X_t} \right) \right] = \mathbb{E} \left[g \left(x \frac{X_T}{X_t} \right) \mid \mathcal{F}_t \right] \\
&= \sum_{q_1, \dots, q_n=0}^{\infty} g \left(x_1 e^{\sum_{j=1}^n (\beta_{1j} q_j - (e^{\beta_{1j}} - 1) \lambda_j (T-t))}, \dots, x_n e^{\sum_{j=1}^n (\beta_{nj} q_j - (e^{\beta_{nj}} - 1) \lambda_j (T-t))} \right) \prod_{i=1}^n \frac{\lambda_i^{q_i}}{q_i!} (T-t)^{q_i} e^{-\lambda_i (T-t)}
\end{aligned} \tag{103}$$

The equalities follow from the definition of $v(p)$ above and of $u(t, p)$ in equation (90) together with the two formulae following it.^c We clearly have $f(T, x) = g(x)$ and

$$F_t := u(t, P_t) = f(t, X_t) = \mathbb{E}[g(X_T) \mid \mathcal{F}_t] \tag{104}$$

Since $u(t, p) = f(t, x(t, p))$, the deltas in equation (102) are given by partial differences of $f(t, x)$ as

$$\begin{aligned}
\delta_t^i &= \delta_i(t, X_{t-}) \quad \text{where} \\
\delta_i(t, x) &:= \frac{1}{x_i} \sum_{j=1}^k \alpha_{ij} (f(t, e^{\beta_{1j}} x_1, \dots, e^{\beta_{nj}} x_n) \\
&\quad - f(t, x))
\end{aligned} \tag{105}$$

We have unique pricing since $(X, 1)$ is arbitrage free (as X^i are martingales). Specifically, if $\hat{\delta}$ is another SFTS for $(X, 1)$ with payoff $\hat{F}_T = g(X_T)$, then $\hat{F} := \sum_{i=1}^n \hat{\delta}^i X^i + \hat{\delta}^m = F$ provided that either all $\hat{\delta}^i$, $i \leq n$ are bounded or all $\hat{\delta}^i - \delta^i$, $i \leq n$ are bounded.

Indeed, then $\hat{F} = \hat{F}_0 + \hat{\delta}' \cdot X$ is a martingale, since X is square integrable (in the second case, also use that F is a martingale). Hence, $\hat{F} = F$ as $\hat{F}_T = F_T$.

Moreover, if $k = n$ we have unique hedging, that is, $\hat{\delta} = \delta$ for any bounded SFTS $\hat{\delta}$ for $(X, 1)$ with payoff $\hat{F}_T = g(X_T)$. Indeed, $\hat{F} = F$, as before; thus, setting $\theta^i := \hat{\delta}^i - \delta^i$ gives

$$\begin{aligned}
0 &= d(\hat{F} - F) = \sum_{i,j=1}^n \theta^i \theta^j d\langle X^i, X^j \rangle \\
&= \sum_{i,j=1}^n \theta^i \theta^j X_-^i X_-^j \sum_{l=1}^n (e^{\beta_{il}} - 1)(e^{\beta_{jl}} - 1) \lambda_l dt
\end{aligned} \tag{106}$$

the last equality following from equation (98). However, the $n \times n$ matrix $(\sum_{l=1}^n (e^{\beta_{il}} - 1)(e^{\beta_{jl}} - 1) \lambda_l)_{i,j=1}^n$ is nonsingular. Therefore, $\theta^i = 0$, that is, $\hat{\delta}^i = \delta^i$ for $i \leq n$, implying $\hat{\delta}^m = \delta^m$ too as $\hat{F} = F$.

One shows, as in the section Exponential-Poisson Exchange Option Model, that the processes δ^i are bounded if $\gamma_i(x)$ are bounded, where

$$\begin{aligned}
\gamma_i(x) &:= \frac{1}{x_i} \sum_{j=1}^k \alpha_{ij} (g(e^{\beta_{1j}} x_1, \dots, e^{\beta_{nj}} x_n) - g(x)), \\
\gamma_m(x) &:= g(x) - \sum_{i=1}^n \gamma_i(x) x_i
\end{aligned} \tag{107}$$

Homogeneous Exponential-Poisson SFTS

Let $A > 0$ be an m -dimensional semimartingale with $A_- > 0$ and set $X := (A^i / A^m)_{i=1}^n$, $n := m - 1$, as before. Assume that

$$dX_t^i = X_{t-}^i \sum_{j=1}^k (e^{\beta_{ij}} - 1) (dP_t^j - \lambda_t^j dt) \tag{108}$$

where $1 \leq k \leq n$, β_{ij} are constants with the $n \times k$ matrix $(e^{\beta_{ij}} - 1)$ of full rank, $\lambda^j > 0$ are bounded predictable processes, and P^j are semimartingales with $[P^j, P^l] = 0$ for $j \neq l$ such that $[P^j] = P^j$, $P_0^j = 0$, and $P^j - \int \kappa^j dt$ are local martingales for some locally bounded predictable processes $\kappa^j > 0$. Assume further that $\mathbb{E} \exp \left(\sum_{j=1}^k \int_0^T \left(\frac{\lambda_t^j}{\kappa_t^j} - 1 \right)^2 \kappa_t^j dt \right) < \infty$.

Owing to the above growth condition, the positive local martingale

$$\begin{aligned} M &:= \mathcal{E} \left(\sum_{j=1}^k \int \left(\frac{\lambda^j}{\kappa^j} - 1 \right) (dP^j - \kappa^j dt) \right) \\ &= e^{-\sum_{j=1}^k \int (\lambda^j - \kappa^j) dt} \prod_{s \leq \cdot} \left(1 + \sum_{j=1}^n \left(\frac{\lambda_s^j}{\kappa_s^j} - 1 \right) \Delta P_s^j \right) \end{aligned} \quad (109)$$

is a martingale. Define the measure $\mathbb{Q}$ by $d\mathbb{Q} = M_T d\mathbb{P}$. As in the section Exponential-Poisson Model Uniqueness, $\int \lambda^j dt$ are the $\mathbb{Q}$ -compensator of P^j . This, equation (108), and boundedness of λ^j imply that X^i are $\mathbb{Q}$ -square integrable martingales. Thus, A is arbitrage free. As before, the SDE (108) integrates to

$$X_t^i = X_0^i e^{\sum_{j=1}^k \beta_{ij} P_t^j - (e^{\beta_{ij}} - 1) \int_0^t \lambda_s^j ds} \quad (110)$$

Now assume λ^j are constant. Then P^j are $\mathbb{Q}$ -Poisson processes with intensities λ^j and are independent since $[P^j, P^l] = 0$, $j \neq l$. Let $h(a)$, $a \in \mathbb{R}_+^m$, be a homogeneous function of linear growth. Define $g(x) := h(x, 1)$, $x \in \mathbb{R}_+^n$. The section Projective Exponential-Poisson SFTS applied under $\mathbb{Q}$ implies that δ given by equation (105) (with $\delta^m = F - \sum_{i=1}^n \delta^i X^i$) is an SFTS for $(X, 1)$ with price process $F = (f(t, X_t))$ satisfying $F_T = g(X_T)$, where $f(t, x)$ is defined explicitly by equation (103), or equivalently, $f(t, x) = \mathbb{E}^{\mathbb{Q}} g(x X_T / X_t)$. Therefore, by numéraire invariance, δ is an SFTS for A with price process $C := A^m F$ satisfying $C_T = A^m g(X_T) = h(A_T)$ by homogeneity.

Assume finally that the payoff function $h(a)$ is such that the functions $\gamma_i(x)$ defined in equation (107) are bounded (e.g., $h(a) = \max(a^1, \dots, a^m)$). By the section Projective Exponential-Poisson SFTS, if $k = n$, then δ is the unique bounded SFTS for A with payoff $C_T = h(A_T)$. In general, since A is arbitrage free, $\hat{C} = C$ for any other bounded SFTS $\hat{\delta}$ for A with payoff $\hat{C}_T = h(A_T)$, where $\hat{C} := \sum_i \hat{\delta}^i A^i$.

End Notes

^aClearly, then the restriction of (any such) $c(t, a)$ to the support of A is unique, and if $\hat{c}(t, a)$ is any function that equals $c(t, a)$ on the support of A , then $C_t = \hat{c}(t, A_t)$ too.

If the support of A_t is a proper surface, for example, if $m = 2$ and A^2 is deterministic as in the Black–Scholes model or $A_t^2 = a_2(t, A_t^1)$ as in Markovian short-rate models, then obviously there exist infinitely many nonhomogeneous functions $\hat{c}(t, a)$ such that $C_t = \hat{c}(t, A_t)$. (Such a homogeneous function also exists under some assumptions as in the section Homogeneous Continuous Markovian SFTS.)

^bIndeed, first assume that A is arbitrage free and let S be a state price density. The martingale $M := \frac{SA^m}{\mathbb{E}[S_0 A_0^m]}$ clearly satisfies $\mathbb{E} M_T = 1$. Hence, the equivalent measure $\mathbb{Q}$ defined by $d\mathbb{Q} = M_T d\mathbb{P}$ is a probability measure.

Since $MX^i = \frac{SA^i}{\mathbb{E}[S_0 A_0^m]}$ is a martingale, X^i is a $\mathbb{Q}$ -martingale by Bayes' rule. Conversely, assume that X^i are $\mathbb{Q}$ -martingales for some $\mathbb{Q}$. Define $M_t := \mathbb{E} \left[\frac{d\mathbb{Q}}{d\mathbb{P}} \mid \mathcal{F}_t \right] > 0$. Then (the right continuous version of) $M = (M_t)$ is a martingale (so $M_- > 0$). By Bayes' rule MX^i are martingales since X^i are $\mathbb{Q}$ -martingales. Set $S := M/A^m$. Then $S, S_- > 0$ and $SA^i = MX^i$. Thus S is a deflator, as desired. Further, since SC is a martingale for any bounded SFTS δ , by the Bayes' rule $SC/M = C/A^m$ is a $\mathbb{Q}$ -martingale.

^cThe projective option price function $f(t, x) := \mathbb{E} \left[g \left(x \frac{X_T}{X_t} \right) \right]$, also encountered for the log-Gaussian case in equation (75), satisfies $f(t, X_t) = \mathbb{E}[g(X_T) \mid \mathcal{F}_t]$ in general when X is the exponential of any n -dimensional process of independent increments (inhomogeneous Lévy process), but we no longer have hedging in general.

Binomial Tree

This model, introduced by Cox *et al.* [1] in 1979, has played a decisive role in the development of the derivatives industry. Its simple structure and easy implementation gave analysts the ability to price a huge range of financial derivatives in an almost routine way. Nowadays its value is largely pedagogical, in that the whole theory of arbitrage pricing in complete markets can be explained in a couple of pages in the context of the binomial model. The model is covered in every mathematical finance textbook, but we mention in particular [4], which is entirely devoted to the binomial model, and [2] for a careful treatment of American options.

The One-period Model

Suppose we have an asset whose price is S today and whose price tomorrow can only be one of two known values S_0, S_1 (we take $S_0 > S_1$); see Figure 1. This apparently highly artificial situation is the kernel of the binomial model. We also suppose there is a bank account paying a daily rate of interest r_1 , so that \$1 today is worth $\$R = \$(1 + r_1)$ tomorrow. We assume that borrowing is possible from the bank at the same rate of interest r_1 , and that the risky asset can also be borrowed (sold short, in the usual financial terminology). The only other assumption is that

$$S_1 < RS < S_0 \quad (1)$$

If $RS \leq S_1$, we could borrow $\$B$ from the bank and buy B/S shares of the risky asset. Tomorrow these will be worth at least $S_1 B/S$, while only RB has to be repaid to the bank, leaving a profit of either $B(S_1 - RS)/S$ or $B(S_0 - RS)/S$. Both of these are nonnegative and at least one is strictly positive. This is an *arbitrage opportunity*: no initial investment, no loss and the chance of a positive profit at the end

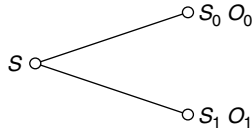

Figure 1 One-period binomial tree

(see **Arbitrage Strategy**). There is also an arbitrage opportunity if $RS > S_0$, realized by short-selling the risky asset.

A *derivative security*, *contingent claim*, or *option* is a contract that pays tomorrow an amount that depends only on tomorrow's asset price. Thus any such claim can only have values, say O_0 and O_1 corresponding to "underlying" prices S_0, S_1 , as shown in Figure 1.

Suppose we form a portfolio today consisting of N shares of the risky asset and $\$B$ in the bank (either of both of N, B could be negative). The value today of this portfolio is $p = B + NS$ and its value tomorrow will be $RB + NS_0$ or $RB + NS_1$. Now choose B, N such that

$$\begin{aligned} RB + NS_0 &= O_0 \\ RB + NS_1 &= O_1 \end{aligned} \quad (2)$$

There is a unique solution as long as $S_1 \neq S_0$, given by

$$N^* = \frac{O_0 - O_1}{S_0 - S_1}, \quad B^* = \frac{1}{R}(O_0 - NS_0) \quad (3)$$

With these choices, the portfolio value tomorrow exactly coincides with the derivative security payoff, whichever way the price moves. If the derivative security is offered today for any price other than $p = RB^* + N^*S$ there is an arbitrage opportunity (realized by "borrowing the portfolio" and buying the option or conversely). Thus "arbitrage pricing" reduces to the solution of a pair of simultaneous linear equations.

It is easily checked that $p = (q_0 O_0 + q_1 O_1)/R$ where

$$q_0 = \frac{RS - S_1}{S_0 - S_1}, \quad q_1 = \frac{S_0 - RS}{S_0 - S_1} \quad (4)$$

We see that q_0, q_1 depend only on the underlying market parameters, not on O_0 or O_1 , that $q_0 + q_1 = 1$ and that $q_0, q_1 > 0$ if and only if the no-arbitrage condition (1) holds. Thus under this condition q_0, q_1 define a probability measure Q and we can write the price of the derivative as

$$p = E_Q \left(\frac{1}{R} O \right) \quad (5)$$

Note that Q , the so-called *risk-neutral* measure, emerges from the “no-arbitrage” argument. We said nothing in formulating the model about the probability of an upward or downward move and the above argument does not imply that this probability has to be given by Q . A further feature of Q is that if we compute the expected price tomorrow under Q we find that

$$S = \frac{1}{R}(q_0 S_0 + q_1 S_1) \quad (6)$$

showing that the discounted price process is a Q -martingale. This is summarized as follows:

- Under condition (1) there is a unique arbitrage-free price for the contingent claim.
- Condition (1) is equivalent to the existence of a unique probability measure Q under which the discounted asset price is a martingale.
- The contingent claim value is obtained by computing the discounted expectation of its exercise value with respect to a certain probability measure Q .

Much of the classic theory of mathematical finance (see **Fundamental Theorem of Asset Pricing; Risk-neutral Pricing**) is concerned with identifying conditions under which these three statements hold for the more general price models. They hold in particular for the multiperiod models discussed below.

The Multiperiod Model

More realistic models can be obtained by generalizing the binomial model to n periods. We consider a discrete-time price process $S(i)$, $i = 0, \dots, n$ such that, at each time i , $S(i)$ takes one of $i + 1$ values $S_{i0} > S_{i1} > \dots > S_{ii}$. While we could consider general values for these constants, the most useful case is that in which the price moves “up” by a factor u or “down” by a factor $d = 1/u$, giving a recombining tree with $S_{ij} = Su^{i-2j}$ where $S = S(0)$; see Figure 2 for the two-period case. We can define a probability measure Q by specifying that $P[S(i+1) = uS(i)|S(i)] = q_0$ and $P[S(i+1) = dS(i)|S(i)] = q_1$ where q_0 and q_1 are given by equation (4) above; in this case, $q_0 = (Ru - 1)/(u^2 - 1)$, $q_1 = 1 - q_0$. Thus $S(i)$ is a discrete-time Markov process under Q with homogeneous transition probabilities. Specifically, it is a *multiplicative random walk* in that each
